I see also that Mr. Sutton, after describing the alkaline development, of which we have heard so much in your own and other journals, and in Major Russell's last edition, concludes, comically enough, by claiming the process in an off-hand, incidental manner, by conjuring his readers to "give our process a fair trial!"

I tried the alkaline process, described by Mr. Bartholomew, with some success, but I did not find the plates keep, and there was a tendency to stains; but with alkaline development and tannin plates I have had a fair share of success, with very few drawbacks. I have never obtained anything like the rapidity of the wet process, but have been able to get good results, with half, and in some instances, with a third of the exposure necessary in the ordinary mode of development. The method with which I have had the greatest success is that which you described as practised by Mr. England a few months ago.* The chief difficulties I have found consist in a tendency to fog, if too much alkali be used, or if the plate be under-exposed, and the alkaline pyro-solution be applied a long time to bring out detail.

Regarding the origin of the alkaline principle it is very difficult to decide. The suggestion of Mr. Bartholomew undoubtedly seems to enunciate the very principles which are now gaining recognition, and was the first broad statement of the idea that alkaline conditions, generally regarded as so inimical to success with collodion plates, might possibly be in dry-plate photography absolutely necessary to the best and most rapid results. But these conditions had nevertheless been used at an earlier date. In July, 1861, we published an article on certain experiments we had made with a process suggested by the Rev. J. Lawson Sisson, in which the preservative was a mixture of borax and gum. Now borax, although by constitution an acid salt, has, nevertheless, an alkaline reaction, and behaves in many respects like an alkali. In our hands the plates so prepared gave very rapid results, but were occasionally apt to fog, behaving in many respects like the gelatine alkaline dry plates. Mr. Bartholomew is an able and ingenious experimentalist, to whom photographers are largely indebted, and, had his suggestion been followed out earlier, would probably have led earlier to results similar to those now obtained. But, as we have before observed, we think that to both Mr. Leahy and Major Russell, as well as Mr. Bartholomew, is due the credit of independent discovery in the matter of alkaline development.

In our own recent experiments we have used some plates which had been forwarded to us as defective, being covered with singular markings. They were coated with a commercial bromo-iodized collodion prepared for the wet process; excited in a thirty-grain bath; well washed, and coated with a fifteen-grain solution of tannin. They had been prepared about three months when we used them. The light was, unfortunately, of the most unsuitable quality; a dull, yellow, misty light, in which it would have been impossible to get

* See *PHOTOGRAPHIC NEWS*, p. 253 of the present volume, May 29th.

brilliant results by any method. With a single lens of twelve inches focus, and a half-inch stop, we gave one plate an exposure of five minutes, with a subject to which we should have given about two minutes and a half with a wet plate and iron development, and to another eight minutes. To one or two other plates we gave an exposure of forty seconds with a Dallmeyer's No. 1 B lens, and a half-inch stop; the light requiring a twenty-second's exposure with wet plates. We also exposed some plates under a negative for about five seconds to diffused light, and for about thirty seconds close to the light of a fish-tail gas-burner. As the plates had not received any preliminary coating we gave each an edging of varnish to prevent the films slipping.

We then proceeded to develop: having moistened a film with common river water, we applied a solution containing four grains of bicarbonate of soda in an ounce of water. In about a minute, if the plate had been fully exposed, a dim phantom of the image was seen; if not very fully exposed no image is seen at this stage. A three-grain solution of pyrogallic acid is now applied, and the image is quickly seen looking vigorous and red by reflected light, but without any density whatever when examined by transmitted light. When all the detail is fully out, the plate is thoroughly washed, and a two-grain solution of pyrogallic acid with a few drops of citro-nitrate of silver applied until the proper intensity is obtained, which, if the proper conditions exist, is secured without difficulty. Mr. Sutton recommends after washing away the alkaline pyrogallic solution, that an ordinary pyrogallic solution, containing acetic acid, but no silver, be applied first in order to prevent any fog when the solution containing silver reaches the film. If the plate have been fully exposed, and all the detail is well out, this may be done with safety; but if there be any lack of detail, it is better not to apply the acid solution without silver, as it prevents the further development of any latent detail which may exist. Instead of applying the solution of bicarbonate of soda first, the plain pyrogallic acid solution may be applied, which will educe a phantom image, and on the addition of the soda solution, will rapidly acquire detail and apparent force; and may be intensified as before.

Those plates which have been exposed the right time, progress under the treatment described in all respects satisfactorily, a clean, soft and forcible image being obtained, of a reddish black tone, the image quite in the film, without any appearance of superficial deposit. Indeed, the film looks bright and polished, and might be smartly rubbed without disturbing it. All the transparencies presented this appearance and some of the negatives. The two plates exposed in the worse light, and with a landscape lens, were not satisfactory. That which has the shortest exposure looked fogged from pushing the development, and that which had a longer exposure, was flat and unsatisfactory from a universal deposit in the film having almost the appearance of over-exposure. We have before noticed that with some dry plates, no amount of exposure in a bad foggy light is of any avail. Those plates exposed with the portrait lens, were a trifle under exposed, but developed satisfactorily, and with out fog or stains.

Where a plate after fixing lacked vigour, we found no difficulty in intensifying by first applying a solution of iodine and iodide of potassium in water, followed by iron, citric acid, and silver.

We used carbonate of soda in preference to liquid ammonia, which we had used before, because we found that it gave us less trouble with rotten or tender films. Carbonate of ammonia, which Major Russell, who has so thoroughly worked the process, recommends, we have not yet tried carefully.

The stains and markings to which we referred at the commencement of this article are very curious. We have heard of them two or three times, and had seen some slight resemblance to them, but not in such a degree. They appeared in some plates like mackerel markings; in others they assumed an arborescent appearance, like the branches

of a tree, the markings being much thicker and denser looking than the rest of the plate, which appeared opalescent, whilst they seemed creamy. The collodion used was very thick, and gave a horny film, and it appeared possible that to its impermeable condition the markings were due. Strange to say, however, with the treatment we have described, there was no appearance of the markings whatever in the finished negatives. Last week we received a communication from a very skilful photographer, who has been very successful with tannin plates, complaining of something similar, but which appears during development. All is described as working well for the wet process, but in the tannin plates mottled skies appear, as if the tannin solution had not taken kindly to the excited film, and had only permeated it imperfectly, notwithstanding the utmost care in manipulation and formula. We submitted the case to Major Russell, in the hope that his experience might suggest the cause and remedy. He has not, however, met with the difficulty; but suggests the use of a larger proportion of alcohol in the tannin solution, and allowing it to remain longer on the plate. If the tannin solution had been washed off, he adds, then doing that imperfectly might cause the mottling, thorough washing being necessary to secure an evenly sensitive surface. The nearest approach Major Russell has seen to such markings is a defect produced by washing the plate with hard water before the free nitrate was fully removed with distilled water, and in that case the markings had a dull appearance by reflected light.

In another page we give a letter from Major Russell, on a new form of difficulty and its remedy.

NEW DRY PROCESS—CATECHU AS A PRESERVATIVE.

BY W. S. CRAIG.

HAVING made some trials in quest of a preservative in the dry collodion process, of easy preparation, good keeping qualities, and rapidity of effect, I was induced to think this was most probably to be found in some vegetable product containing the requisite proportions of tannin, extractive matter, and mucilage. I made a trial of a decoction of lentiscus leaves, the result of which was encouraging, but there appearing to be a deficiency of tannin, I made a trial of a decoction of sumach, which was a decided improvement; and, perhaps, more from curiosity than necessity, I made a third trial with a decoction of catechu, the result of which left nothing further to desire, and I have now been using it with invariable good success for the last two years.

In landscapes my exposure is thirty seconds with a single lens, 13½-inch focus, and half inch diaphragm; and with a good light, I can take instantaneous views with the stereoscopic camera.

Heat is favourable to the process, and seems to accelerate its operation. I have, by way of experiment, left the landscape camera for four minutes under the influence of a blazing sun, when the thermometer marked 84 in the shade; of course the resulting negative was over-done, but still usable; and I may notice, in conclusion, that I have kept some of the preservative for upwards of a year, and that it is still as good as ever.

With this brief preface, I will now proceed to describe my process.

Preservative.

Boiling, distilled or rain water 20 fluid ounces

Pulverised catechu ... 400 grains.

Mix and stir well, when cold, filter through cotton wool, measure the resulting decoction, and add 10 per cent. of alcohol, strength 39 Beaume.

Collodion.

The collodion I use, and which I make myself, is by Robiquet's formula, only I have considerably increased the quantity of the bromide of cadmium in it. My receipt is as follows:—

Gun cotton	159 $\frac{3}{10}$ grains
Gun flax	39 $\frac{3}{105}$ "
Amber varnish	637 $\frac{6}{5}$ "
Alcoholic extract of gum-lac	159 $\frac{1}{15}$ "
Iodide of cadmium	198 $\frac{2}{10}$ "
Bromide of "	144 "
Ether... ..	63 cubic inches
Alcohol	15 $\frac{8}{10}$ "

Coating the Plate.

Coat the plate and excite as usual. I give three minutes in the nitrate bath.

On taking the plate from the bath, immerse it in a tray of water, rock it gently about half a minute, repeat the process in a second tray, after which pour water over it, so as to free it completely from free nitrate, and prevent stains. Now pour on the preservative, flow it round and round for about half a minute, pour it off again, wash the plate freely, and set it aside to dry.

Developer.

Pyrogallie acid	1 $\frac{1}{2}$ grains
Citric acid	3 " or 60 acetic acid.

Pour this once or twice on and off the plate, then add about one-fourth of a 10-grain nitrate solution, pour this over the plate; the image will now appear, and rapidly acquire the requisite intensity.

The catechu I make use of appears to be the Malabar, the only kind I can get here.

Cagliari, September 24th.

THE MANUFACTURE OF PHOTOGRAPHIC COLLODION.*

BY W. L. NOVERRE.

THE IODIDES AND BROMIDES.

The iodides and bromides most suitable for bromo-iodized collodion are those of cadmium, ammonium, and lithium.

The iodide of cadmium is an exceedingly stable salt, and collodion iodized with it will remain colourless for a very long time, the reason of its not being more generally used is the property it possesses of making collodion thick, so that it has to be kept several months in the iodized state before it becomes sufficiently fluid for use; it is, however, very valuable, when mixed with the less stable iodides; it tends to make the collodion set more quickly on the plate than an alkaline iodide. Bromide of cadmium is stable like the iodide, and does not thicken collodion in the same manner.

Iodide of ammonium is an unstable salt; it rapidly liberates iodine from collodion and renders it limpid; it is usually met with in crystals of a yellow colour, due to free iodine. This may be removed by washing the crystals in ether and drying them on blotting paper. This iodide is useful for mixing with iodide of cadmium, as it counteracts the property, which the cadmium salt possesses, of thickening collodion. The bromide of ammonium is not unstable, like the iodide, and is preferred by some to the iodide of cadmium.

Iodide of lithium is an opaque, colourless salt, exceedingly deliquescent, and must therefore be kept in a closely stoppered bottle. It possesses the advantages of the cadmium and ammonium salts, without their drawbacks. Thus it has little effect in causing the liberation of iodine from collodion, and, like ammonium, renders it limpid and structureless. Collodion iodized with iodide of lithium turns a pale lemon colour after a few days, and remains without further change for many months, provided the salt is pure, and that the plain collodion is not acid. Iodide of lithium retards the setting power of collodion, a desirable quality in hot weather. This property can be modified at will by using it in conjunction with iodide of cadmium. Bromide of lithium does not appear to possess any advantage over the bromide of cadmium, and is much more expensive.

THE BROMO-IODIZED COLLODION.

The proportions of alcohol and ether that will be found most convenient for general purposes are two parts of the former to one part of the latter; this is a larger proportion of alcohol than is usually recommended, but the formula will be found to possess many advantages. As has already been shown, ether is a very unstable substance, therefore the less of it there is in the collodion the longer may it be expected to keep without decomposing. A collodion containing a large proportion of alcohol is very valuable for coating large plates, and for general use in hot weather, as it enables the operator to coat the plate leisurely, and the fumes of the ether, which are very irritating to the eyes, are not felt during the operation, which is a great boon to the photographer who has to work in a tent or other confined space. It has been alleged by some that an excess of alcohol in collodion is injurious to sensitiveness—this is not found to be the case when using pyroxyline of the kind that has been described, and when a bromo-iodizer is employed. With regard to the kind of iodide used affecting the sensitiveness of the collodion, much diversity of opinion prevails; there does not appear, however, to be any perceptible difference, provided each is used when it has reached its most sensitive condition. With regard to the effect of various iodides on the keeping properties and upon the mechanical state of the collodion, sufficient has already been said.

The normal collodion is prepared as follows:—

Pyroxyline	18 grs.
Ether (sp. gr. .725)	1 oz.
Alcohol (sp. gr. .805)	1 "
Alcohol (sp. gr. .820)	1 "
Iodide of lithium	7 $\frac{1}{2}$ grs.
Iodide of cadmium	6 "
Bromide of cadmium	1 $\frac{1}{2}$ "

Place the pyroxyline in a bottle, add the alcohol (sp. gr. .805), and shake up till the cotton is wetted, then add the ether, and agitate till solution of the cotton is complete; next dissolve the iodides and bromide in the alcohol (sp. gr. .820), and add to the collodion, shake the whole together, and put it by in a dark place to settle down. The cotton, if properly prepared, will dissolve entirely in the mixture of ether and alcohol, and when the collodion is perfectly bright and clear, it may be drawn off from the sediment at the bottom of the bottle with a glass syphon as already described. It will be fit for use after it has been mixed for a week or ten days, and will gradually improve for a month or more. Collodion should be kept in the dark, or it will become ozonized, liberating iodine, which tinges it a yellow colour. This will often disappear again on placing it in the dark. When the clear collodion has been drawn off, a plate should be coated and sensitized. If it is found to give a pale opalescent film, and to repel the developer, the alcohol was too strong, and two or three drops of water must be added to each ounce of collodion, in order that it may give a more creamy film; if too much water is added, the film will be reticulated. It must be remembered that bromides have a tendency to produce an opalescent film.

Collodion used soon after iodizing will often give a picture covered with pinholes, and having a deposit on the transparent parts of the negative. Pinholes may be often prevented by filtering the iodizing solution before adding it to the plain collodion, and the deposit on the shadows can be obviated by adding a little tincture of iodine till the collodion is of a pale sherry colour.

Collodion prepared by the above formula will keep for many months in the iodized state without deterioration.

If it is intended for use soon after mixing, for coating large plates, it will perhaps be necessary to reduce the quantity of pyroxyline to five grains per ounce of solvents, or iodide of lithium may be substituted for the quantity of iodide of cadmium given in the formula, which will in-

crease the limpidity of the collodion. If the collodion is only intended to keep for a few months, iodide of ammonium may be substituted for the iodide of lithium in the formula, as the latter is a very expensive salt. If ether of a higher specific gravity than that advised in the formula is used, a little more of the strong alcohol must be substituted for that of sp. gr. .820.

The proportion of bromide given in the formula is sufficient to make the collodion work cleanly without reducing its intensity, but it will be found advisable to increase the proportion of bromide when the light is strong, or in photographing objects presenting powerful contrasts of light and shade, and for instantaneous work. For certain subjects, equal quantities of iodide and bromide may be used, and as much as 4 grains bromide to 2 of iodide have been employed with advantage for particular purposes. Collodion should not contain more than 6 grains of iodide and bromide together, so that, when it is desired to use a large quantity of bromide, a certain proportion of plain collodion must be added to combine with the excess of iodide. A table is given below, by which a collodion containing any proportion of iodide and bromide may be obtained ready for immediate use. The solutions required are the normal bromo-iodized collodion, plain collodion, and the same with a bromide dissolved in it. These are numbered respectively 1, 2, and 3, for convenience in reading the table. The quantity selected is about eight ounces, being considered a convenient quantity.

THE SOLUTIONS.

1. *Normal Bromo-Iodized Collodion*, containing $4\frac{1}{2}$ grains iodide and $\frac{1}{2}$ grain bromide per ounce.

2. *Plain Collodion*.—Pyroxyline 15 grains, ether (sp. gr. .725) 1 ounce, alcohol (sp. gr. .805) 1 ounce, alcohol (sp. gr. .820) 1 ounce.

3. *Bromo-Iodizing Solution*.—Dissolve 24 grains bromide of cadmium or ammonium in 1 ounce of No. 2 solution.

Number of grains of iodide and bromide per ounce the collodion is required to contain.		Quantity of No. 1 solution to be taken.	Quantity of No. 2 solution to be taken.	Quantity of No. 3 solution to be taken.	Quantity obtained of the collodion desired.
Iodide.	Bromide.				
$4\frac{1}{2}$	$\frac{1}{2}$	8 ounces.	—	—	8 ounces.
$4\frac{1}{2}$	1	8 "	—	4 scruples.	8 ounces 4 scruples.
$4\frac{1}{2}$	$1\frac{1}{2}$	8 "	—	8 "	8 ounces 8 scruples.
4	2	7 "	$\frac{1}{2}$ ounce.	$\frac{1}{2}$ ounce.	8 ounces.
3	3	6 "	2 "	1 "	9 ounces.
	4	$3\frac{1}{2}$ "	$3\frac{1}{2}$ "	$1\frac{1}{2}$ "	8 ounces.

It is hoped that the details which have been given will not appear tedious. The manufacture of collodion of uniform character is a nice operation, and one requiring care and great method in every part of the process. If the directions given in this paper are carefully followed out, a failure can scarcely occur.

AURO-CUPRIC TONING BATH.

BY C. OMMEGANCK.

Most of the toning baths at present employed present certain difficulties of management, because they are not fit for use as soon as prepared. It is necessary for the chloride of gold they contain to be more or less deprived of its chlorine by the contact of some alkaline salt, without which, the proofs submitted to its colouring action are weakened. We can easily accelerate the decomposition by slightly warming the

bath solution for immediate use, but how frequently it happens that it becomes heated too much or too little, and moreover, a warmed bath never tones so well, nor lasts so long as one in which the exchange of the chlorine has been made slowly, at ordinary temperature. How many times have we found ourselves embarrassed with a bath, either too new, or which has lost its strength by the effect of the heat of the atmosphere, and at a loss what to do when we have had proofs to tone, whether the bath should be prepared the day before or some days in advance?

By warming the bath, we therefore uselessly complicate operations already sufficiently difficult; a toning bath is really only practically useful when it can be prepared at the moment of using.

This object may be obtained by various formulæ, but the following appears to us the most advantageous of all, on account of its simplicity, of the great rapidity of its colouring power, and the facility with which we can obtain every desirable tint.

Water	35 $\frac{1}{2}$ ounces
Chloride of gold	7 $\frac{1}{2}$ grains
Deuto-chloride of copper	1 $\frac{1}{2}$ "
Carbonate of soda, sufficient to produce an alkaline reaction.				

By varying the quantities of chloride of gold and chloride of copper, we obtain a variety of tints from black to blue grey, with all the intermediate tones.

The bath is prepared in the following manner:—Dissolve in aqua regia 90 grains of metallic gold, and add from 50 to 75 grains of common salt, then evaporate to dryness by a gentle heat, and dissolve in $3\frac{1}{2}$ ounces of water. This gives a solution of about 10 per cent., 6 parts of metallic gold giving about 10 parts of chloro-hydrate of chloride of gold.

In the next place, dissolve 75 grains of metallic copper in aqua regia, and evaporate the solution to dryness by a gentle heat. 5 parts of metallic copper give about 10 parts of deuto-chloride of copper; dissolved in $35\frac{1}{2}$ ounces of water, it gives a cupric solution of 1 per cent.

If the salts are bought ready made, dissolve 15 grains of chloride of gold in 3 fluid drachms of water and 15 grains of chloride of copper in 30 drachms of water.

Pour into a suitable dish a volume of water corresponding to the bath required; for each 100 parts of water add $\frac{1}{2}$ part of the gold solution and 2 parts of the cupric solution. Put in a piece of litmus paper, which will become red in a few minutes; then add, drop by drop, a solution of pure carbonate of soda, and stir. When neutralized, the litmus paper will recover its blue colour. The bath is now ready for use, and will keep good several hours. When its energy begins to slacken, the addition of a few drops of the solution of chloride of gold will revive it, but it is necessary to be assured that the reddened litmus paper continues to turn blue after this addition of chloride of gold.

Before immersing the proofs, we commence by soaking them in a small quantity of water, in which they may remain some time without inconvenience; then they are placed in a larger quantity of water for a few seconds, and afterwards passed rapidly through a third quantity of water. Lastly, they are immersed in the toning bath, and continually moved about, especially during the first moments of their immersion, and frequently examined. If any proofs are noticed with red spots arising from contact with greasy fingers, remove them from the bath, place them in water, and dry them with filtering paper. Then pass a pencil dipped in a solution of carbonate of soda (saturated) over the spots; leave them for a minute, immerse them in water, return them to the toning bath, and the spots will have disappeared. The number of proofs that may be saved by this simple operation, which would necessarily have been lost, will certainly form a rich collection.

As the proofs are removed from the toning bath they are collected in a water bath. When all are toned they are

fixed in a fresh solution of hyposulphite of soda—strength 15 to 20 per cent. An immersion of 5 minutes is generally sufficient. At the end of this time the proofs are fixed, and have resumed the hue they had before being placed in the hypo. The transparency of the paper in the whites also indicates to a certainty the entire solution of the salts of silver incrustated in the pulp of the paper. Prints over-printed, and which are generally regarded as lost, are treated like the others, but they are left in the hypo as short a time as possible, until their transparency is complete. They are then washed in two waters, and immersed in a saturated solution of hypo. They rapidly lose their colour, and are not less permanent and beautiful than the others. It is also a means of obtaining detail from negatives too thick in the lights. We have only to print to a bronze colour, except in the whites, and then fix as described above.—*Bulletin Belge de la Photographie.*

ON THE MEASUREMENT OF THE CHEMICAL ACTION OF DIRECT AND DIFFUSE SUNLIGHT.

BY R. W. BUNSEN, FOR. M.R.S., AND H. E. ROSCOE, B.A.*

IN one of the four communications which the authors have already had the honour of presenting to the Royal Society on the subject of the measurement of the chemical action of light, the attempt was made to determine experimentally the laws regulating the distribution of the chemical action of the sunlight and diffuse daylight on the surface of the earth when the sky is perfectly unclouded and the atmosphere clear. The methods of measurement there employed do not, unfortunately, apply to the much more usually occurring case of cloudy skies and hazy atmosphere. The aim of the present communication is to describe an entirely different mode of measuring the chemical action effected at any point on the earth's surface by the total sunlight and diffuse daylight, under the most widely varying conditions of situation, climate, and state of the atmosphere.

In spite of the various futile attempts which have been made to register and measure the chemical action of light by means of photographic tints, it still appeared possible in this way to attain the desired end. No instruments founded on such a mode of measurement can yield reliable results, unless we know the conditions under which photographic surfaces of a constant degree of sensitiveness can be obtained, and unless the relations be determined which exist between the degree of tint produced, and the time and intensity of the light acting to effect such a tint.

The first point which the authors examine, is whether the photographic tints produced vary in shade in the direct ratio of the intensities of the acting light. Several experiments proved that no direct ratio between the degree of blackening and the intensities of the light exists. Hence it is necessary to relinquish the idea of employing any mode of measurement founded on the comparison of photographic tints of different shades. The next point examined is whether equal shades of blackness always correspond to equal products of the intensities of the acting light into the times of insolation. For the purpose of testing the truth of this proposition, an instrument is employed, by which photographic sensitized paper can be exposed for times, which can be exactly measured to within small fractions of a second. This instrument consists essentially of a pendulum vibrating about $\frac{2}{3}$ seconds, by whose oscillation a sheet of darkened mica is withdrawn from, and brought back over, a horizontal strip of paper prepared with chloride of silver, and fixed in a constant position relative to the pendulum and sheet of mica. The time during which each point in the length of the strip is exposed is different, and the time of insolation for each point can be calculated when the length and position of the strip, and the duration and amplitude of the pendulum's vibration is given. A table exhibits for each

millimetre in length of the strip, as measured by a scale attached, the time of exposure in seconds, which the corresponding point of the strip undergoes in one vibration of the pendulum. These numbers require to be multiplied by n , if the paper has been insolated for n vibrations.

The paper insolated whilst the pendulum is oscillating, exhibits throughout its length a regularly diminishing shade from dark to white; and the time of insolation of any point is found by reference to the table. If we wish to determine which of these shades corresponds to another tint produced by a separate insolation, we cannot make the comparison by daylight or ordinary lamplight, as these lights produce considerable changes of tint in the sensitive paper. The two shades may, however, be perfectly and safely compared by the light of a bright soda-flame; this light possesses the great advantage of being chemically inactive, and likewise of rendering imperceptible those slight differences of colour which make the comparison of two shades by the ordinary light so difficult.

In order to compare any other photographic tint with the point of equal shade on a strip, the latter, together with its millimetre scale, is attached to a board, in a darkened room. The board slides in a groove, so that it can be moved horizontally; and in front of the paper strip a small block holds in a fixed position a small piece of the tinted paper which it is desired to compare. On throwing the light of a bright soda-flame upon both surfaces, it is easy, by moving the board from side to side, to find the exact point at which the shade of the strip is identical with that of the other tinted paper. It is then only necessary to consult the table in order to find the time in seconds during which the paper must have been exposed in order that it should attain the tint in question. A series of lights of known intensities was obtained, by allowing the sun to shine through holes of known size. The images thus formed fell on to a piece of prepared paper; and the tints produced were compared with a strip darkened in the pendulum apparatus, and thus the time of exposure necessary to effect the shade determined. Experiments made with intensities varying from 1 to 50, show that within these limits equal shades of blackness correspond to equal products of the intensities of the acting light into the times of exposure; so that the light 1 acting for the time 50, produced the same degree of blackening as the light 50 acting for the time 1.

A method for measuring the chemical action of light by simple observations is then founded upon this proposition. Thus, if we assume as the unit of photochemical action that intensity of light which produces in the unit of time a given degree of shade, we have only to determine, on a strip of paper tinted in the pendulum apparatus, the point where the shade of the strip coincides with the given tint; the reciprocals of the times which correspond to these points of equal shade give the intensities of the light expressed in terms of the above unit.

This method of measurement is available only—

1. If the phenomena of photochemical induction do not interfere with the blackening of the paper.
2. If a photographic surface of a constant degree of sensitiveness can be prepared.
3. If an unchangeable tint can be obtained which can be exactly compared with the photographic paper.

The result of a series of experiments made by varying the number of the vibrations and calculating the intensity from each observation, showed that photochemical induction does not exert any prejudicial effect upon the measurements.

The question into which the authors enter at greatest length as being the most important for determining the exactitude of the measurements, relates to the mode of preparing a standard paper possessing a constant degree of sensitiveness. The relative degree of sensitiveness is determined by exposing the papers to one and the same light for the same length of time, and then comparing their tints with the shades of a strip prepared in the pendulum—

* *Philosophical Magazine.*

apparatus, fixed in a solution of hyposulphite of soda, and furnished with an arbitrary scale. The influence of the strength of the nitrate of silver solution upon the sensitiveness is first examined; a series of experiments shows that with the same homogeneously salted paper, the sensitiveness of the film does not alter when the strength of the silver solution varies from 8 to 10 or 12 parts of nitrate of silver to 100 of water. Further examination showed that the time during which the paper lies upon the surface of the silver bath may vary from 15 seconds to 8 minutes, without any difference in the sensitiveness of the paper being noticed; and no difference is found by the employment of silver solutions which had been long in use and those freshly prepared. The papers thus silvered may be preserved for from 12 to 15 hours in the dark without undergoing any change in their sensitiveness.

If the paper be allowed to float on the surface of the solution of chloride of sodium, as on that of the silver bath, the sheet after silvering exhibits, on drying, a very unequal degree of sensitiveness in its various parts. If, on the contrary, the sheet be well soaked in the salt-bath no such irregularity appears, and the sheet is of an equal degree of sensitiveness throughout its whole surface. This fact is determined by several extended series of experiments. The effect of change of concentration of the salt-bath upon the sensitiveness of the film is very great; and, as far as the observations extend, no limit exists beyond which an increase or a diminution of the percentage of salt in solution ceases to affect the sensitiveness of the film. Hence, in order to obtain constant results, it is necessary to employ a solution of chloride of sodium of constant strength. By using solutions of the same strength, papers of a constant degree of sensitiveness are obtained.

The influence of the thickness of the paper employed is next examined. Experiment shows that differences in the thickness of white paper, such as is usually employed for photographic purposes, is without influence upon the sensitiveness of the film of chloride of silver.

The changes in atmospheric temperature, from 3° C. to 50° C., and in atmospheric moisture, are likewise found not to influence the sensitiveness of the prepared paper.

From the experimental results detailed in the communication, it appears that, by adhering to a certain mode of preparation, a standard paper can be obtained, which at all times possesses a degree of sensitiveness sufficiently constant for the purposes of exact measurement. In the following extract from a larger table, the readings are given which were made from papers prepared in three different salt solutions of the strengths mentioned, and silvered in a solution containing 12 of nitrate of silver to 100 of water. Equality in the numbers in each of the columns III. and IV. denotes equality in the readings and in the tint, and therefore equality in the sensitiveness of the prepared surfaces. Three sheets of paper were dipped into each solution. These numbers likewise show the great degree of accuracy with which tints can thus be compared.

I. Paper.	II. Na Cl to 100 parts of water.	III. Intensity No. 1.	IV. Intensity No. 2.
Upper part of sheet No. 2	3.026	87.0	75.4
Middle part of sheet No. 3	2.950	86.3	74.4
Middle part of sheet No. 2	3.028	86.0	74.9
Lower part of sheet No. 2	3.000	85.9	74.4

The next subject considered is the preparation of an unvarying tint which can be easily obtained and used as the standard of comparison. This is effected by grinding together 1,000 parts of pure oxide of zinc with 1 part of pure lamp-black. A series of experiments showed that a colour can thus be prepared which possesses a constant and unalterable shade; and this can be used as a measure of the standard tint.

Having proved that a standard photographic paper of constant sensitiveness, and a standard tint of unvarying shade can be prepared, it is only necessary to apply the proposition that equal products of the intensities of the light into the times of insolation effect equal shades of blackness, in order to find a method of comparative measurement of the chemical action of the total daylight. As the *unit* of measurement, the authors propose to adopt that intensity of the light which in one second produces the standard tint of blackness upon the standard paper.

When the standard paper is insolated in the pendulum-apparatus, a strip is obtained which is tinted with every gradation of shade from dark to white. If the point on this strip is determined which coincides in shade with a paper covered with the standard tint, we have only to look into the Table to obtain the time of insolation (*t*), in seconds, which is necessary to produce the shade corresponding to the reading on the millimetre scale. If this time of insolation were found to be one second, the intensity of the light then acting would be $I=1$; for any other time the intensity of the chemical rays would be $\frac{1}{t}$.

As an example of such measurement, the authors append three series of observations, giving the total amount of chemically active rays falling on a horizontal surface at Manchester in summer and winter, made at intervals of 10 minutes throughout three separate days. These observations are likewise graphically represented as curves, which show maxima and minima exactly corresponding to the appearance and disappearance of the sun; and from them some idea may be formed of the vast differences which occur in the intensity of the chemical rays falling on the earth's surface during the longest and shortest days.

In conclusion, the authors state that it is possible, by using the pendulum-apparatus, to construct a portable instrument by means of which a large number of observations can be made upon a few square inches of paper. They reserve the description of their instrument for a future occasion.

PRINTING, TONING, AND FIXING DIRECT POSITIVES ON ALBUMENIZED PAPER.*

AMMONIO-NITRATE of silver is more sensitive to light than nitrate of silver, as is also the chloride of silver produced by double decomposition with ammonio-nitrate of silver and any of the alkaline chlorides; it produces more vigorous pictures, and sensitizes the paper more quickly than the simple nitrate of this metal.

2. These are very important qualities in photography; it has, however, its disadvantages or difficulties, which are the following:—Free ammonia easily dissolves the albumen from the surface of the paper, whereby the solution becomes discoloured, forming albumenate of silver; this deteriorates the effectiveness of the solution for future operations; the paper is reduced again to plain salted paper, and the picture is mealy, imperfect in the middle tones, and possesses but very little vigour.

3. The question, therefore, arises: How can the ammonio-nitrate process be modified so as to obviate these disadvantages? We have experimented with various reagents, such as ether, hot water, acids, &c., and have selected, as successful in a high degree, the following method, by which the albumen surface is preserved entire, the tone is a rich purple black, all meanness or snowiness avoided, and uniformity of action maintained.

Silver Bath.

4. Dissolve one ounce of nitrate of silver in six ounces of rain water; of this solution take two ounces, and add ammonia until the precipitate is redissolved; afterwards mix these with the remaining four ounces. Now add four drachms of alcohol and allow the oxide of silver to settle. If any particles still swim on the solution, remove them by drawing a small sheet of paper two or three times over the surface. It is not necessary—it is not even injurious—to filter the solution; for the sediment is oxide of silver, which is afterwards dissolved by the addition of ammonia.

* From Humphrey's Journal.

The paper, already cut and prepared according to art, is made to float on the silver for about ten seconds; all bubbles and particles that may adhere are carefully removed from its surface, and afterwards it is dried in the usual manner. Every time this bath of silver is again used fresh crystals of the nitrate are added together with a few drops of ammonia and about one drachm of alcohol.

Toning.

5. The prints are first well washed in several waters; the operation may be performed in ten minutes or a quarter of an hour; if the time is much longer, the tone is impaired. They are then passed through hot water previously to their immersion in the toning solution. This solution is formed as follows:—From the stock bottle containing one part citrate of soda and six parts water, take two ounces; to this add one pint of warm water, one ounce of rain water, holding in solution one grain of chloride of gold, or more, according to the number of prints to be toned, and two drachms of alcohol. The toning soon commences, and is soon finished if the gold is of sufficient quantity. The temperature must be preserved at a blood-heat, or about 100° Fah.; if it were greater the gold would become decomposed, and the solution blackened instead of the prints; if lower, the time of operation will be prolonged, and the operation itself tedious. The alcohol in this solution prevents all action of the alkali on the albumen, whereby the vigour of the print is preserved. We do not use the same bath twice unless immediately, and then of course with the addition of more gold. After the toning is finished, any gold that may remain is reduced by sulphate of the protoxide of iron, and collected.

Fixing.

6. The fixing medium consists of the ordinary solution of hyposulphite of soda. Every time I use this bath I add fresh crystals of this salt, two drachms of alcohol and an ounce or two of warm water. The prints, previous to their immersion in this bath, are again passed through warm water. The colour of the prints is not much changed when the prints are introduced, or if slightly changed, they soon regain their original and final tone. In two or three minutes the prints will be sufficiently acted upon by the hyposulphite, and are then removed into the water bath and thoroughly washed. The material point in these preparations is the use of alcohol in each subdivision; because upon this reagent success depends. Carbonate of soda may be used instead of citrate in the toning solution; the tone, however, is a richer purple black with the latter than with the former.

I would finally remark that unless the negative be properly and successfully taken with due contrast of light and shade, and without a universal fogginess over the whole surface, deep purples or blacks can never be obtained by any process; the silver salt has to be thoroughly acted upon by light in order to receive the desired toning.

Proceedings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

The first meeting of the Society after the summer recess was held on the evening of Wednesday, Sept. 23rd, in Myddelton Hall, Islington; Mr. G. DAWSON, M.A., in the chair.

The minutes of a former meeting were read and confirmed, after which the following members were duly elected:—Mrs. Verchoyle, the Rev. A. B. Cotton, F. W. Hart, and A. Harman.

No paper having been provided for the evening, the proceedings were of a conversational and desultory character.

Mr. G. WHARTON SIMPSON brought under the attention of the meeting the new process introduced by M. Beyrich, of Berlin, for removing the albumen film containing the image from a print on prepared paper and transferring it to a plain or curved surface, or glass, porcelain, &c. He exhibited one or two specimens, and explained the *modus operandi*. (For details, see the PHOTOGRAPHIC NEWS, of Sept. 4th, page 421.) He also showed some prints from which the film had been removed, but which still contained very deeply printed images, although of a redder tint than the film which had been removed.

A long and desultory conversation on the process and the purposes to which it might be applied, followed. After which, the question of their probable permanency was discussed, several members suggesting that photographic experience of

albumen was not favourable to the idea of permanency where it was employed. After some conversation on the superior permanency of developed prints and negatives, especially these on waxed paper.

The CHAIRMAN expressed his conviction that this superior permanency was due to the nature of the deposit, which in developed prints consisted of metallic silver, whilst in ordinary prints it was probable that it consisted of a sub-chloride or a sub-oxide. He had some waxed paper prints which were done twelve years ago, and which were not very carefully washed, and these had not faded at all; whilst ordinary prints, taken at the same time, and more carefully treated, were all gone.

Mr. SHAVE made some confirmatory remarks, and observed that the wax probably aided in protecting them.

Mr. HART referred to the fact that wax paper negatives were developed with gallic acid, and said that he had some very early collodion positives, which were developed with pyrogallic acid, which were not in the slightest degree faded.

Mr. SIMPSON said, he believed that carefully kept collodion pictures, either positive or negative, were quite permanent. Probably, in developed pictures, there was a more perfect deposit of metallic silver; but if the mere fact of the presence of metallic silver were regarded as a guarantee of permanency, it might be argued by those who, with Mr. Spiller, denied the sub-chloride theory, that, as all prints consisted of metallic silver, all ought to be permanent.

The CHAIRMAN said there was some essential difference in the deposit. Albumen negatives, however, were also apt to fade. Some taken by Rees and Thompson's process, in 1852, had faded, whilst waxed paper negatives, taken at the same time, were quite permanent.

Mr. SIMPSON: And yet the albumen negatives were developed with gallic acid?

The CHAIRMAN: Yes.

Mr. SIMPSON said, that would suggest that it was the albumen which was the cause of the decay.

The Rev. A. COTTON asked how long albumenized paper had been used for prints, and who first introduced it.

The CHAIRMAN said it was used prior to 1853. He did not know who first used it.

Mr. W. W. KING said he believed Mr. Henry Pellock did.

Mr. SIMPSON said, that in this country it was generally claimed for Mr. POLLOCK; the French also claimed the introduction, he believed, for Legray.

After some further conversation on applying the film to vases of various shapes, varnishing, &c.,

Mr. MARTIN asked if it could be burned in, and what would be the effect of submitting the image, as shewn, transferred to enamel glass, to the fire.

Mr. SIMPSON said, as the image there consisted chiefly, if not entirely, of metallic gold, substituted for silver in the process of toning, the effect of burning would be to destroy the albumen, leaving a thin purple image of gold burnt in. But the image would probably be somewhat thin and feeble, when the organic basis was destroyed. It might possibly happen that, if a flux of powdered glass, which melted at a very low temperature, were placed over it, and then submitted to the fire, a vitreous surface might be secured at a lower temperature than would be necessary for the deflagration of the albumen.

After some further conversation,

The CHAIRMAN made some remarks on the general prosperity of the Society. He regretted the absence, through illness, of Mr. Shadbolt, and was sure that all sympathised with that gentleman. As a Society, he thought they were a model for the imitation of some others, in the harmony which at all times prevailed in their meetings. He regretted, however, the general reluctance of members to prepare papers, and was confident that every one met with unexplained and interesting phenomenon continually, which might be profitably discussed, if duly recorded. If photographers would make a practice of carefully observing abnormal results, and noting all the conditions, they would gradually make a pile of information, which would bring photography into the position of a science, as certain as logic or mathematics.

Mr. SIMPSON showed some card pictures of the new solar camera arrangements devised by Mr. Stuart, of Glasgow, dispensing with the mirror, and making the condenser and machine generally follow the sun.

The CHAIRMAN said that Mr. Stuart had unquestionably produced the finest solar camera pictures that he had seen.

Mr. SIMPSON also showed a number of very fine card pic-

tures, by Mr. Parkinson, of Dieppo, and Mr. Hughes, of Rydo, to illustrate the peculiar quality of tone obtained by the use of lime in the toning bath.

The prints having been examined and much admired,

Mr. HISLOP asked what strength of nitrate bath was used in producing them? The subject of weak baths had recently been brought under discussion by Mr. Taylor, who intimated that good results might be obtained with a 20-grain solution. He had himself made some experiments and found that the prints produced with a 30-grain bath, and with a 100-grain bath, were equal in vigour and general character. The paper was then *Rive*, and he left it on the 30-grain bath as long as a quarter of an hour. The subject was a most important one, especially to amateurs, for where large sheets had to be excited, requiring a large quantity of solution, it became an expensive operation if a strong bath were imperative.

Mr. SIMPSON had made some experiments during the summer with weak solution, but for a different purpose. Finding that during the hot weather the excited paper very quickly became discoloured, he tried a weak solution, not much exceeding 20 grains to the ounce, with a trace of nitric acid. He found that paper excited on this solution would keep, even in hot weather without discoloration. With vigorous negatives he obtained, very good pictures with more half-tone than he could with a stronger solution; but if the negatives were weak, the prints were not so good, and there was a greater tendency to meanness. The object of using a strong bath was, however, to obtain vigour, as rapid excitement was considered to keep the image well on the surface of the paper. With ordinary albumenized paper, containing 8 or 10 grains of salt to an ounce of albumen solution, it was clear that very strong nitrate baths were not necessary to decompose all the chloride, and form chloride of silver. But whilst weak baths, requiring long floating, were apt to dissolve the albumen, and also to allow the silver solution to soak in, strong baths, rapidly rendered the albumen insoluble, and completed the formation of the sensitive salts of silver on the surface, thus securing an important condition of brilliancy. He was in the habit of using a weak bath with hard negatives, and a strong one with weak negatives.

Mr. HART thought long floating injurious, as the paper got thoroughly saturated with solution, instead of remaining on the surface.

Mr. HARMAN had had a great deal of experience in printing, and he found that a short floating on a strong solution gave the greatest brilliancy. With good negatives it was always possible to get good results. It was the weak or poor negatives which really tried a process.

Mr. SIMPSON said that landscape photographers who generally secured the most brilliant negatives had not the same troubles to contend with as the portraitist, who must operate frequently in a dull, feeble light, and must print such negatives as he could get. He believed Mr. Hislop's negatives were generally good ones and not deficient in vigour.

Mr. COTTON had found it a good plan to remove the paper from the exciting solution as soon as it ceased to curl, hang it up to dry, and then give it a second floating. Paper so treated gave great vigour, and the process involved no loss of time, as there need be very little time wasted in waiting.

Mr. HISLOP said some of the negatives he had used were portraits, and not very vigorous.

After some further conversation in which Mr. Hislop recommended to the attention of members an article by Professor Roscoe in the *Philosophical Magazine*. (See PHOTOGRAPHIC NEWS, p. 473).

The CHAIRMAN said he had not experimented largely with weak baths, but he thought when there was long floating it was probable that the nitrate combined not only with the albumen, but also with the size, and that favoured rapid decomposition and discoloration of the excited paper.

Mr. HARMAN preferred a 100-grain bath, and floating for 15 seconds.

The CHAIRMAN suggested that the subject be thoroughly discussed at the next meeting, and Mr. Harman undertook to bring a number of specimens floated various periods on different solutions for comparison.

Mr. HISLOP referred to the use of nitrate of soda which had been proposed in weak baths.

The CHAIRMAN said its action was curious. In water it would dissolve albumen, and, added to a weak solution of nitrate of silver new, it would dissolve the albumen; but when it had accumulated in an old and weak bath by the ordinary pro-

cess of exciting, the weak solution did not dissolve albumen, and it certainly, under those circumstances, added to the vigour of the print.

After some further conversation,

Mr. SIMPSON asked if any one had tried the American suggestion for using oxide of silver dissolved in nitrate of ammonia.

The CHAIRMAN said that, although claimed by the Americans as a discovery, it was not new. Mr. Archer used it in 1854 with plain paper.

Mr. SIMPSON showed some very fine specimens by Mr. Blanchard, produced to illustrate the working of his collodion with simple iron development without intensifying. These were much admired.

Mr. BOCKET, kindly brought for distribution amongst the members a number of card pictures of a pictorial "Life of Christ," consisting of a series of pictures, representing events in the Gospel narratives, skilfully arranged to form one complete tableau. This had been cleverly photographed so to form a good card picture.

The proceedings were then concluded.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, September 30th, 1863.

Among the various applications of photography, perhaps few are of more interest or importance than that to the science of Anthropology. M. Potteau, of the Museum of Natural History, lately presented to our Photographic Society a large number of proofs, representing most of the soldiers belonging to the battalion of indigenous sharpshooters, styled *Tureos*, and to the squadron of *Spahis*, now in Paris. In placing these interesting studies before the Society, M. Potteau pointed out the most striking differences which characterise the races to which these soldiers belong.

Among other donations recently made to our Society, may be mentioned a stereoscope made by Mr. Dallmeyer, of London, presented by M. le Comte Nostitz, and a number of transparent positives to accompany the stereoscope. These pictures the donor obtained last year, during a journey he made in the government of Orenbourg, by the Wolga.

The United States Patent Office has presented a copy of its Report on the Progress of Industry, in the various States of the Union, for 1860. This work is in two octavo volumes, illustrated with 643 plates, and contains a description of all the patents granted during that year.

M. Hamy communicated the following remarks upon the means he proposes to employ, to avoid sulphuration of paper positives, taken upon salts of silver:—

It is very generally known that proofs fixed in hyposulphite of soda, are sometimes covered at the time of fixing, but more frequently after long exposure to the air, with a film of sulphur which destroys the picture. The chemical nature of this deposit, and the progress of its formation, are still but imperfectly understood; but it arises either from the decomposition of the fixing agent, or it may be attributed to a portion of the salt of silver which has not disappeared during the washings; it belongs to science to point out the means by which we may eliminate the last traces of hyposulphite of soda, or the complex hyposulphite of soda, silver and gold.

Now the only means of removing all the sulphur that may remain in the state of hyposulphite will be to convert this substance into a compound without action upon the colourless and soluble metallic film. Chlorine, it appears to me, should produce this result. No one, in fact, can be ignorant that put in contact with a hyposulphite, it causes all the sulphur to pass into sulphuric acid. Here, however, a difficulty presents itself in the inevitable formation of a little chloride of silver, if any of the hyposulphite of this metal remains in the proof. Besides, it forms some hydrochloric acid, which may have an injurious influence upon the

albumen. A simple washing in a dilute solution of ammonia will remove these two inconveniences. For the quantity of chloride of silver, which can be formed after the first fixing, is relatively minute, and, as for the hydrochloric acid, it will be completely removed in the washing, or become neutralized by the ammonia.

M. Regnault, the President, remarked that the process proposed by M. Hany, appeared to be very judicious in theory, but it was to be feared that in practice the chlorine would not confine its action to the hyposulphite in excess, but attack and chloridize the feeble portions of metallic silver, constituting the half-tones.

M. Moisson communicated to the Society the result of some experiments he had made upon the vitrification of negatives. M. Laulerie thought, that if we could preserve in the vitrified cliché, all its primitive delicacy, it would then be in a condition of permanence hitherto unknown; he therefore employed M. Moisson to make some experiments, which were successful, and M. Moisson exhibited to the members present, a negative, the yellow image on which is due to the incorporation of the silver, constituting the ordinary image, with the glass itself. A number of positives taken from this negative, show the benefit we may expect to derive from the method in the preservation of negatives. M. Moisson added that the glass most suitable for operations of this kind, is that with a potash base, called *verre à peindre* by glass-workers.

FORMIC ACID IN THE DEVELOPER.

SIR,—I certainly did understand your correspondent as experimenting with Mr. Claudet's process, and mistaking or mis-stating the formula.

He confirms my view by saying in his letter, without date, in your last issue, "I used a developer as recommended by Mr. Claudet."

A developer is only a subordinate part of a process, and in saying he used it as recommended by Mr. Claudet, I, of course, understood him to mean in the manner and under the conditions recommended by Mr. Claudet; viz., to develop an iodized collodion. It now appears that he did not use it as recommended by Mr. Claudet at all, but as recommended by yourself in the month of June. Then, why does he "merely think you will agree with him" as to a fact which you yourself informed him of three months ago? But he does not appear to read up what goes on in photography, as he says, "he had been led to suppose that no one could succeed with bromo-iodized collodion and pyro-formic acid developer." And this, in spite of your making known the exact contrary in June. It is this loose and vague way of writing, without sufficient information, that gives so much trouble to amateurs, who are led astray by false conclusions and incorrect statements.

But Sergeant Moss says, "It can but be a matter of indifference to me, so long as I can work successfully in the way laid down in my letter, who approves of it or who does not." I had fancied he wrote for his photographic brethren's information and guidance.

But it appears that the question is now narrowed to the fact whether or not Sergeant Moss can himself work successfully in the way laid down (not by him but by yourself), in June last; a matter, I think, hardly worth discussion to the public in general. But there is another point on which he might seriously mislead a young photographer. In his first letter he describes the pyro-formic negative as "fine, clear, well-defined, with deep shadows; perhaps, if anything, very slightly under-exposed;" the iron negative, "full of detail, but flat compared with the preceding one." In his second letter the pyro negative had "shadows a very little too deep," but it had as much detail as the iron negative, already described as "full of detail." If full of detail, how could it have been under-exposed? and how could the shadows be too deep? the deepest shadow in a negative full of detail being points of bare glass.

But to yourself, Mr. Editor, who know what an iron negative ought to be, is it not clear that the iron negative is the best, or at all events the most rapidly produced? Sergeant Moss, in his vague way, says nothing about the intensification of the iron negative. If not intensified, it would necessarily be weak and flat, taken in a bath such as he describes, if at all over-exposed. If it was intensified and still flat, that points more strongly still to over-exposure; if the intensification was properly conducted I cannot but think, therefore, that the pyro-formic negative was under, and the iron one over, exposed, according to Sergeant Moss's own showing, and that the iron developer thus proved itself the more rapid of the two.

You, sir, will, I think, agree with me that an iron negative very frequently does look flat till intensified, because, looking through an iron negative in its first stage, the gradations of opacity are so very delicate as to give it a flat appearance, but under the proper intensification, as the opacity of the whole increases, the *relative* opacity of the high and medium light increases in a different proportion till your finished negative is a good one in all points. This can be shown by printing from an iron negative after the iron only, then printing from a certain amount of intensification, then again after more intensification. This is a very instructive lesson to beginners as to the difficulty of judging an iron negative in its first stage.

I should have been glad to have entered more fully on this subject, but your space would not admit of it. I have said thus much, as I think Sergeant Moss is not conversant with good iron negatives, and his statement as to the goodness of the two negatives much calculated to mislead.—

Faithfully yours,

H. STUART WORTLEY, Lieut.-Col.

September 28.

IMPERFECT PHOTOGRAPHIC GLASS.

DEAR SIR,—In the PHOTOGRAPHIC NEWS of last week, some important statements were made respecting the modes of cleaning glass plates, and the character of surface often presented by such as have been repeatedly employed in the photographic processes. Your correspondent, Mr. R. T. Back, refers specially to the corrosion of new plates, and attributes the roughening of the glasses to the circumstance of their having been packed with intermediate sheets of paper. I have never myself experienced this difficulty, but have often had occasion to remark the facility with which some kinds of glass become decomposed or etched, by the action of water, and other more powerful chemical solvents.

Some years ago, I made experiments upon spun glass, which had then recently been proposed as an electric insulator for submarine cables, and was certainly not prepared to find that this material immediately furnishes alkali to pure water, and when left in contact for some time (in a platinum vessel), gives up an appreciable amount of soluble matter. The same result is observed when ordinary crown glass is pulverised and triturated with water, the alkali thus removed can be detected at once by red litmus, or turmeric paper. In the case of more powerful solvents, chemists are aware that caustic and carbonated alkalies quickly corrode glass, as do also liquid ammonia and solution of phosphate of soda: in the bottles used for the preservation of the two latter solutions, flakes of detached silica are usually seen floating. With the knowledge of these facts, I do not consider it wise to adopt the recommendation in your last from *Humphrey's Journal*, viz., to immerse the glass plates for several hours in a solution of "salt of tartar" (carbonate of potash); and I know by experience that patent plate is much injured by being left for a day or two in a solution of carbonate of soda. If alkali be required for the cleaning of glass plates, I should much prefer the use of cyanide of potassium, since this agent dissolves likewise the traces of a former picture, or any compound of silver, remaining as a contamination upon the surface of the plate. It is equally effectual in the removal

of soap and grease, and acts almost the part of an universal solvent. Nitric acid diluted with an equal bulk of water, answers well for dissolving the metallic impurities, and is not liable to corrode the glass. In all cases, it is, however, of great importance to avoid leaving the glasses for a long time in contact with any of these liquids, since the destruction of the first polish seems to prepare the way for a more energetic action upon the vitreous substratum. I am, Sir, yours very truly,

JOHN SPILLER.

Royal Arsenal, Woolwich, September 28th, 1863.

DEAR SIR,—For the benefit of Mr. Back and others, I beg to forward you the following remedy for dirty glasses. Wash them well in water, then wipe them dry; rub them with a cloth dipped in a saturated solution of chloride of lime; polish them without rinsing, then breathe on them, and many would be tempted to use them, but would repent it probably afterwards. Next pour on them a strong solution of iodine and iodide of potassium, which will be sure to develop such a beautiful crop of patches, to all appearance as greasy as if some fatty matter had only just been applied. No amount of rubbing will remove them, neither will nitric acid applied pure. The remedy is this: wipe them dry, dip a cloth in a saturated solution of cyanide of potassium, well rub them, rinse, wipe, and again apply the iodine and iodide of potassium solution, and you will find them free from all greasiness; but before you have quite done with them, try the usual test of breathing on them.

Now I am writing, I may as well tell you how I secure my pneumatic holder from occasionally sending my glasses to destruction. I boiled a lump of gutta percha in water, and when quite soft applied it to the top of the holder, bringing it below the rim, and moulding it a good thickness. I then made a hole in the centre of the gutta-percha for the brass pin, and forced the face flat on a piece of plate glass, well wetted with water; and when the gutta-percha was hard, I trimmed it into shape, held the polish face to the fire until sticky. I then applied the india-rubber and pressed it on a piece of glass, as before, and when the gutta-percha was thoroughly hardened, I put in the pin, with button at the top, and screwed all in order. Thus doctored, mine will hold good, like the old passports, for a year and a day.—Yours, truly,

A SUBSCRIBER *ab initio*.

PRIZES AT THE ROYAL CORNWALL POLYTECHNIC SOCIETY.

DEAR SIR,—Will you kindly state in your next impression that a 1st silver medal was awarded to Colonel Stuart Wortley for his beautiful collection of photographs. The paragraph in your last rather implies that it was a medal of a lower value than Mr. Robinson's, which was not the case. The judges had the highest possible opinion of the merits of Colonel Stuart Wortley's pictures, which for artistic effect were considered finer than any hitherto produced.—I am, dear sir, yours faithfully,

SYDNEY HODGES.

Secretary to the Royal Cornwall Polytechnic Society,
Falmouth, September 28, 1863.

[Our allusion to the medals was given in the exact words of a private letter, written by a gentleman connected with the society, and was not meant, we feel sure, to imply any want of merit in Colonel Stuart Wortley's pictures, which are truly described as "magnificent specimens." We have before recorded our opinion of these pictures as unquestionably the finest of the kind which have ever been produced, and it can be no derogation of Mr. Robinson's position as a first medallist, on so many occasions, for the best picture, to receive now the companionship of Colonel Stuart Wortley as first medallist for such a collection of pictures. We have since incidentally heard that Messrs. S. Thompson, J. H. Morgan, and Dr. Tressider each received a bronze medal. We should have been glad if Mr.

Sydney Hodges' letter had conveyed an official statement of the photographic prizes given, and their due relation. The communication of the gentleman who kindly undertook to furnish us with full particulars, has, through unfortunate delay or miscarriage, not yet reached us.—Ed.]

WANT OF INTENSITY IN TANNIN PLATES.

DEAR SIR,—A short time ago I met with a difficulty which was new to me in working with washed tannin plates; they would not develop to a sufficient degree of intensity, and became veiled during development. I found that the cause of the fault was the addition of too much ether to the collodion after evaporation by use. On the addition of about $\frac{1}{2}$ ounce of alcohol sp. gr. 805 to $1\frac{1}{2}$ ounce of the collodion, it worked satisfactorily, easily producing ample intensity, and developing much brighter. As I generally use a full proportion of alcohol, I was not before fully aware of the importance of keeping the proportion of ether as low as is consistent with working well.—Yours very truly,

C. RUSSELL.

Romford, Sept. 29th, 1863.

EDEN'S MICROSCOPIC CAMERA.

SIR,—I notice a communication in last week's PHOTOGRAPHIC NEWS, from Mr. Casartelli, of Manchester. It is quite true that I engaged Mr. Potter to make a portion of a small instrument for taking minute pictures to be used as microscopic objects, but Mr. Casartelli is well aware that it would not answer for the purpose. One reason was that the chemical and visual foci were not coincident, consequently it would sometimes take hours to adjust. Mr. Casartelli, after many vain and fruitless efforts to produce pictures as good and as cheap as Mr. Dancer's, abandoned its use in despair. My instrument is totally different from the one I and Mr. Potter constructed. The purpose for which I consider mine most useful is taking enlarged microscopic objects. The adjustment is simple and easy, and the chemical and visual foci being coincident, the most inexperienced can use it. If Mr. Casartelli likes to infringe the patent, he is at liberty to do so, as far as I am concerned, as I have sold my interest in it long ago; but I doubt if the gentleman who purchased it would allow him to do so with impunity.—I am, Sir, your obedient servant,

A. F. EDEN.

Walworth, S., Sept. 29, 1863.

A PHOTOGRAPHER'S RAMBLES.—LIGHT TRIPOD, &c.

MY DEAR SIR,—You will read the date below, and wonder where that is. Canandaigua is an inland village, about three hundred miles from New York, on a beautiful lake, sixteen miles long. The name is Indian, and signifies "a chosen spot." I am rusticated away from the heat and hum of the city. I am duly armed and equipped, of course, as a well-meaning amateur should be, with a Hughes' camera and changing box (the same one I got from Mr. Werge), and sixty extra plates. This I consider a fair supply for one month, as I seldom use more than eight plates during a day's walk, unless it is in some very wild and interesting locality, and then, as I never carry chemicals away from home, I find sixty plates are quite as many as I care to develop on my return. I was at one time enthusiastic enough to average twelve new negatives per day, but I found the negatives accumulated so fast as to drive away all hopes of ever getting pictures printed from them; and I have now in my boxes some negatives made a year ago that have not yet been in the printing frames. I intended to print and send to you, before I left home, prints from negatives taken with the Fitz lens and with the globe lens, but the preparation for departure prevented me, so accept my apology and the promise of them when I return.

We left New York by the Erie Railway, and made a stop

at Homer,—classic name! is it not?—Syracuse, Virgil, Rome, Manlius, &c., are all villages in the neighbourhood. I took my camera to Glenn Haven, a beautiful spot at the head of Skaneateles Lake, and after eating some roast corn and beef in the woods (our party built their own camp fires, and stole the corn) exposed a few plates. The great feature of this section of country is the "Bloomer" dress of the females. (I can't call them women, for they don't look so.) They do not wear the neat Turkish costume, tied at the ankles like those we are told of in the papers; you see no dainty little gaiter boot at the bottoms of silken extremities; no, no, they "wear the breeches;" but they are great ugly cloth breeches and *peg boots*. Only think of a "female human" in your or my broadclothes and boots, with a sort of French blouse reaching not to the knees. I made a demonstration to secure the portrait of a buxom fat girl in this rig, washing dishes at the kitchen door of a house, but she indignantly rushed into the house and slammed the door violently. I had been told that the Bloomer dress was becoming, and ladies proud of wearing it. That certainly did not look like it.

I am using a new tripod made of twelve pieces of gas tube $\frac{3}{8}$ th of an inch thick, and one foot long. These can be carried in a side pocket of a shooting jacket, or strapped with the camera over the shoulder. They screw together at the ends, and make a tripod four feet high, and perfectly firm. They are very convenient to pack away, and take very little space. The trouble of putting them together is, of course, a loss of time, but then, I keep mine set up all day, and shutting the three legs together, carry it with the camera and changing box on its head, in my hand, like a soldier's musket at "trail arms." This Hughes' box is a perfect arrangement, but he manufactures (or used to do so) it too frail, as the wood is so thin that a drop on a stone would smash it, and the rough usage a camera gets in America soon uses it up. My Hughes' box is already dilapidated, and a bottle of glue is my constant pocket companion. More anon.

—Yours respectfully,

F. F. THOMPSON.

Canandigua, N. Y., September 11th, 1863.

Photographic Notes and Queries.

THE FUMING PROCESS.

DEAR SIR,—I see in the NEWS of to-day a little more on the fuming process. I beg to state I have not declined the use of it, having constantly used it for the last two years. My mode of using it is as follows:—I dissolve 40 grains of silver to the ounce, and then precipitate with ammonia, and re-dissolve with nitric acid (I see it reads in the NEWS "re-dissolve with ammonia;" that cannot be right*), with just enough to make it clear; then sensitize for three minutes; then fume for fifteen minutes, in a kind of box I made myself, as follows:—2 feet 6 inches in height, 1 foot square. 4 or 6 inches from the bottom I have put a false bottom with perforations made with a half-inch centre-bit, which I find diffuses the fumes much better. Then I throw the paper on the said perforated bottom, and cover up for fifteen minutes. I find they are very sensitive, and of a cream colour, which does not interfere with the whites. The toning bath is much the same as stated in this week's NEWS, with the addition of a little carbonate of lime, and I find my prints are much richer, and, I believe, more permanent. Enclosed is a print, the first that comes to hand. You can report or not, and I would give any instructions, private or otherwise, as far as lies in my power.—Yours truly, W. H. FOX.

2½ and 50, Park Street, Bristol.

RETAINING THE SPECIMENS OF OPERATORS.

MR. EDITOR,—I wish to call your attention to a practice existing among master photographers of retaining specimens sent them for approval. Now, you are, I have no doubt, aware that they are not so free in allowing their operators to retain many good specimens, and I think it rather hard that those few should be kept.

* Yes; quite right.—Ed.

I advertised a short time since in the NEWS, and had several replies requesting specimens to be forwarded. I did so, and had the greatest difficulty in getting them returned, and one gentleman, not far from Whitehaven, has not condescended the slightest reply to my letter requesting that if not approved of, the cartes were to be returned.

I think a few words from you would cause an alteration.

With many thanks for the many pieces of information I have culled from your valuable paper, I am, Sir, yours, respectfully,

AN OPERATOR.

Greenwich, Sept. 22nd, 1863.

[The practice in question cannot, surely, be common; and is unquestionably most unfair and thoughtless. We think it would be wise to enclose with the specimens an envelope addressed and stamped, so as to leave no excuse on the score of trouble. Few persons would retain cards when such facilities for their return were afforded.—Ed.]

CHALK IN THE TONING BATH.

DEAR SIR,—Your correspondent's question has been answered by yourself; but he is in error when he thinks that I keep a sediment of chalk in the toning bath; I only do so in the concentrated solution, chloride of gold.

I always now use a bath for sensitizing paper made with 30 or 40 grains of silver per ounce, and 60 grains of nitrate of potash, which combination is equal in all respects to a 60 or 80 grain silver solution.—I am, dear Sir, yours faithfully,

Lgham, September 29, 1863.

WM. BARTHOLOMEW.

GUTTA-PERCHA NEGATIVE TRANSFERS.

SIR,—Permit me to refer again to this subject. It is very important to assist travellers, and even if imperfectly, to relieve them from the incumbrance of carrying much glass on a photographic excursion. Gutta-percha, after being some time in solution, deposits its colour. The solution, when used, must be applied strong, and when applied, the plate may be warmed, or the solution, after its application, may be warmed on the plate. A gutta-percha transfer looks shrivelled, like gold-beaters' skin, but when spread out flat and blown on, the creases disappear. If some members of our photographic societies would investigate the subject, many who may have to go a long distance may hereafter be thankful to them.

C. E.

TRANSFER OF FILMS.

I SEE, in your last Number, an inquiry about Mr. Archer's plan of coating negatives with gutta-percha, and taking from the glass. I believe that the principal objection to this otherwise convenient plan is, that in the course of a few months the gutta-percha becomes so brittle that the negative falls to pieces on being touched. Would the mixture of a little india-rubber with the gutta-percha keep it unaltered? The mixture is rather sticky until well dried.

C. RUSSELL.

[The preparation of gelatine and glycerine, recently described in our pages by Mr. Lewis, would probably be found useful.]

Talk in the Studio.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.—Our readers who are members of this Society are reminded that the session re-opens on Thursday evening next, at the City of London College, Leadenhall Street. An opening paper, suited to the occasion, will, we understand, be read by Mr. A. H. Wall.

THE PATENT LAWS.—A striking illustration of the unfair working of the existing patent law was recently given in a judgment delivered by Lord Westbury in reference to the popular Ghost patent. After observing, in the course of hearing opponents to the patent, that he had seen the same principle applied very many years ago, he gave a verdict deciding that the patent should be granted in order that its validity might then be fully contested in a court of law! As to the fairness or unfairness of the patent, we offer no opinion, but surely this is only such a reason for granting a patent as would have occurred to the mind of a lawyer. In an article on the subject, the *Daily Telegraph* pays a handsome, and, we think, a well merited compliment to photographers. It says:—"If each improvement in photography had been at every stage fenced and hampered by patents taken out by successive

inventors, the art would have been strangled in its cradle. Fortunately, the photographers were as generous and unselfish as real men of science usually are, and photography became as free as the air we breathe."

SUBSTITUTE FOR YELLOW GLASS.—A correspondent sends us the following:—Some weeks ago I read in the PHOTOGRAPHIC NEWS of a substitute for coloured glass in the dark room. I forget, at the moment, the name of the gentleman who sent it, but whoever he is, he has my best thanks for publishing so useful a piece of information. I have a window in my dark room (that was) which I almost completely blocked up. When shut up, it was almost dark, and to be locked up in it many minutes was irksome. It was not long after reading the paragraph that I went to the colourman's and purchased the 2 tubes of colour, &c., tore down the old canvas outside the window and the yellow tissue paper that lined it inside (for such was my substitute for yellow light, it answered after a fashion), mixed my colours, and gave the six panes 2 coats in a day, for which the quantity just held out, at a cost of 1s. 4d., and truly can I say your correspondent does not exaggerate; the change from dreary darkness to a flood of golden light was enchanting. I felt quite afraid of exposing my plate in such a flood of light, but have now grown bold and can say it answers perfectly with the sun shining full on the glass; and I must tell you my process is iron development which won't stand fog. I am indebted for many useful hints to your valuable paper, and if you think my experience in this will be useful to your readers, pray use it." [The gentleman to whom our readers were indebted for the hint in question was, if we are not mistaken, Mr. Adlis, who was the unfortunate victim of a fire at the Portland Bazaar, by which he was a severe loser, and needs aid and sympathy.—ED.]

HYPOSULPHITE OF SODA.—In a paper on the manufactures of the district read at Newcastle, it is stated that the manufacture of hyposulphite of soda has largely increased of late years, and we believe in 1838 it was not made at all upon the Tyne. In 1854 the produce only amounted to 50 tons a year. It has gradually risen to 400 tons per annum. In addition to being used in photography, it is largely employed as an "anti-chlor" in papermaking, and from the Tyne the markets of Europe and America are chiefly supplied. In 1852 Mr. W. S. Losh obtained a patent for the manufacture of hyposulphite of soda from soda waste, which has been the means of greatly lessening the price, and consequently extending its application in the arts. On account of its greater stability hyposulphite of soda has nearly superseded the use of the older salt of sulphite of soda as an "anti-chlor," the latter being chiefly confined to sugar refineries as a deoxidizer. Dr. Jullien has recently obtained a patent for the production of hyposulphite of lime, to be used as an "anti-chlor," but it has not yet been introduced in commerce, the apparatus for its manufacture in course of erection at the Jarrow Chemical Works not yet completed.

To Correspondents.

- A. H. W.**—The first meeting of the South London Photographic Society's Winter Session will be held at the City of London College on the evening of Thursday the 8th instant. To become a member you must be proposed by a member. We shall have pleasure in proposing you.
- DEPOSIT.**—Your first difficulty is due to the glutinous character of the collodion; mixing it with a more fluid sample will remove the evil. 2. If you use the formula as you describe it in your letter, we think you are making an error. You state 2 drachms of iron, and 1 drachm of acetic acid to 20 ounces of water. Should it not be ounces of iron and acetic acid? We think that is what you mean when you ask "is not the developer very strong?" It is probable that by slightly decreasing the proportion of iron, and increasing the proportion of acetic acid, you will remove the tendency to the rapid decomposition of the solution which leaves silvery stains on the negative. But the decomposition you describe is frequently due to the condition of the nitrate bath. When it proceeds from this cause, neutralizing the bath by the addition of a little bi-carbonate of soda, sunning for a few hours, and filtering, will probably set it right. 3. We should recommend you to join the Photographic Society, and you will then receive regularly its excellent journal.
- FAIR PLAY.**—Qualifications for practising photography cannot be certainly gauged by the length of experience. Some persons practise for years without ever attaining great proficiency; others become good operators in a few months. Much depends upon natural qualities and previous education and habits. We cannot offer any opinion of the general fitness of the person in question, beyond what was expressed in our comments on his productions.
- HARRISON FRODSHAM.**—The proprietors of the *Illustrated London News*, *Punch*, and similar journals, unquestionably have a copyright in their engravings, and it is unlawful to copy them without acknowledgment. 2. We have not had any experience with the collodion in question. 3. The evaporation of the ether would leave your collodion thick and gelatinous,

but would not leave a "copious woolly precipitate." That looks very like the result of water having been added, which would throw down the pyroxyline. 4. If you mix all your residues together, liver of sulphur should be used to precipitate the silver from the solution as a sulphide. 5. Liver of sulphur is "a polysulphide of potassium." 6. When Mr. England spoke of recovering 40 or 50 per cent., he meant that proportion of the silver originally used.

- J. BUTLER.**—We are uncertain of the address; but the London agent is Solomon.
- W. CHILTON.**—The general design of your intended glass room is good, and if the exigencies of your material and position demand that it should be just as it is, it will do very well. As a matter of choice, we should have preferred the roof of the sitters' division to have been continued without an angle to the roof of division for the camera, and the glass as well. 1. We see no objection to the use of the asphalt felt, but have not had much experience with it. A friend of ours employs it for the covering of a dark room, and it answers very well. 2. We should prefer the triangular piece to be of glass, if equally convenient, as it is undesirable to have two distinct lights falling on your sitter; the side light and top light should, if possible, be a continuation of each other. 3. There is not too much glass.
- J. H. C. 42.**—You will find articles containing valuable information on transparencies in Nos. 139, 140, 188, and 208 of the PHOTOGRAPHIC NEWS.
- G. R. G.**—Place the background at the south end of your room. 2. The print received is pretty good; a little dark, perhaps, in the shadows, and, for our taste, a little too brown, otherwise it is good.
- E. E. D.**—Are you well assured that your bath contained no nitric acid? Any trace of nitric acid, Mr. Blanchard informs us, would decompose the glycerine, and cause fog. We have not had any experience in the matter ourselves, but have seen very fine negatives by the process produced by Mr. Blanchard.
- D. OWEN.**—The yellow tint of your photograph is, probably, due to the use of old and acid hyposulphite of soda, producing sulphur toning.
- D. S. SETTON.**—The chief fault in your specimens is a little tendency to black shadows. This would generally have been remedied by longer exposure. Your carpet is not sufficiently subdued. The vignettes are pretty good. No. 1 is the best, but the shadow on the retiring cheek is a little too heavy. A little more reflected light on the shadowed side of your figures, generally, would be an advantage.
- A. B. W.**—You have, by the free addition of acetic acid and carbonate of soda, formed a large amount of acetate of silver in the bath, which is a frequent cause of streaks and other evils. Try neutralizing with carbonate of soda, and leaving for several days or weeks in a strong light. If, after the filtering it does not work well, your only plan will be to precipitate the silver. 2. We do not know of any efficient card lenses which can be worked at a less distance from the sitter, than the one you have of Dallmeyer's.
- JOHN VANHEUR.**—We will write.
- N. H.**—There are good card lenses which will work in a distance of 15 feet. It would, however, be invidious to mention names here. You will find some mentioned probably in our advertisement columns; or, if you send us a list of names numbered, we can indicate a number.
- F. O.**—Your pictures have some very good qualities. The negatives would have been improved by a trifle longer exposure; and for vignettes it is desirable to use a lighter background. The only advice we can give you on the subject of a partner is to advertise in the PHOTOGRAPHIC NEWS. We cannot tell you the prices of advertisements; but our publisher will communicate with you.
- MICRO-PHOTOGRAPHS.**—MR JAGLIS, 90, Bolsover Street, London, informs our correspondent, John Davidson, that he can give him the information he requires regarding micro-photographs. We will be happy to hear from Mr. Jaglis on the other subject he named.
- AN ENQUIRER.**—A glass room twelve feet long is scarcely suitable for card portraiture, unless you are content to open the door and work with the camera outside. 2. The part immediately above, and at the sides of the sitter, should be opaque for a few feet, say from four feet to eight feet, according to circumstances. 3. We see no objection to placing the glass-house obliquely in your yard, in order to secure the light on your sitter, chiefly from the north. 4. From 10 feet to 15 feet high. 5. A person who has taken the portrait of the Prince of Wales by express permission may, we should think, use the words, "Patronized by the Prince of Wales," and, for anything we know to the contrary, use the emblematic feathers; but we cannot speak with certainty on this subject.

THE USE OF A LENS IN PRINTING.

THE employment of a lens, used as a "burning glass" for concentrating the rays of the sun on some especial part of a negative in order to obtain augmented actinic action, has been frequently recommended; but rarely, we believe, practised. M. Guillaume has, we observe, recently revived the subject in an article in the *Revue Photographique*. As this article has been transferred into the pages of some of our contemporaries, we copy the translation, and add one or two cautions on the subject.

The chief advantage of using a lens in this way is found with an over-intensified negative, in which the face, it may be, or some other important part is so dense that the half-shadows and shadows become buried and black before the detail in the lights is sufficiently printed. The lens, skilfully used, to bring the direct rays of the sun to a focus on the dense parts, may, in such case, secure a good print from a negative which under other circumstances would only yield a worthless, hard, black and white picture. The principle once understood, it will readily be seen that by those willing to devote the time to the work many artistic effects may be communicated to the picture which are not in the negative. We have seen well-designed drawings, which had been executed on sensitive paper without a negative at all by Mr. Rejlander, simply using the light as a pencil.

But it is most important to remember, that when the sun's rays are brought to a focus by a lens, intense heat, as well as great light is produced. The lens becomes a burning glass; and unless great care be used, the varnish is melted, and adheres to the albumenized paper, and the negative is spoiled. Some time ago, we discovered this to our cost. We had used the lens with advantage before, and having a negative which we valued highly, although it was a little too intense in the face, we used the lens again to condense the light for a short time on the face. We used all the precautions which had before given good results, but this time the varnish, a perfectly hard one, melted, and the paper was stuck to the face, and although removed with great care, one of the eyes was irretrievably damaged. We had not taken into account one circumstance which modified the result. We had used the lens before, with a printing frame having a thick glass, through which the heat was a much longer time in penetrating to a dangerous extent. This time the negative was placed in the rabbet, in a small printing frame, fitting it without any glass over it, so that the focus or burning point was on the back of the negative itself, which was thin, and transmitted intense heat through to the film and varnish in a few seconds. It will be seen, therefore, that great caution should be used, when such an aid is used with a valuable negative. We now append M. Guillaume's article:—

It often happens that a negative, satisfactory in all other respects, but obtained under adverse conditions of light, yields prints which are hard and deficient in harmony. The high lights of the face become flat and white, while the more shaded portions do not acquire the desired amount of vigour. Increasing the exposure in the pressure frame, so far from improving, only serves to render more obvious the violent contrast of light and shade. Such a negative should be ruthlessly destroyed, rather than see the proofs it produces unfavourably received.

Frequently, also, in the portraits of ladies, linen, lace, embroidery, and such light accessories—the success of which gives such a charm to reproductions of this nature—being realized in the negative, only produce heavy white masses, the details in which, although visible by transmitted light on the glass, completely arrest the passage of light, which proves too feeble to determine the reproduction of these details on sensitized papers.

Under such circumstances, the greater number of photographers employ screens to shade those parts where the impression is imperfect. This expedient, besides being slow and difficult, does not accomplish the purpose for which it was designed.

The following is the method which we have often adopted, and which, in many cases, has enabled us to obtain with hard negatives proofs by no means deficient in softness and harmonious gradation:—

It is well known that a round magnifying glass, or any other lens, interposed between the solar rays and a plane surface, by concentrating the luminous rays, produces on the surface, placed at a convenient focal distance, an amount of light which causes the surrounding parts, although illumined by the direct rays of the sun, to appear, by contrast, feeble and dull. Now, when our pressure-frame, containing the negative and the sensitized paper is exposed, we furnish ourselves with a burning-glass, attached to a light metallic mount, by means of which we guide what may be called the *luminous point* to those parts of the negative most opaque to light, and in doing this we maintain a constant and uniform motion, so as to avoid the production of marks or lines; and the effect of this condensed light is sometimes so energetic that the most opaque parts of the negative, thus lighted, have acquired the necessary exposure before the more transparent portions are sufficiently printed. We have been able, in this way, to reproduce more delicate details than by ordinary light—details which would, in fact, have become lost in the density of the negative.

Moreover, by this process, vigour may be imparted to a feeble negative by directing the *luminous point* to those parts deficient in relief and modelling,—the shadows of the face, and certain details of drapery, for example. In a view, also, details may be brought out in the façade of a strongly lighted building or column, or other details of architecture or sculpture, which otherwise become lost in the opacity of the negative.

It is unnecessary to add that the *luminous point* must not be stopped for any long time in one place. The great heat produced at the focus of the converging solar rays, although having to pass through the thick glass of the pressure-frame, would affect the delicate collodion film. Finally, the force of the luminous ray may be regulated at pleasure by approaching or withdrawing the lens which produces it.

A NEW PHOTOMETER.

BY M. MALVAL.

WHEN *positive* photographic paper is exposed to daylight, the film of chloride of silver with which it is covered assumes a successive series of hues: pale lilac, deep lilac, light violet, deep violet, &c. It is upon this property of chloride of silver that the new method of photometry is founded. It consists in forming by a suitable mixture of colours a fixed hue identical with one of the hues produced by light upon chloride of silver. This fixed hue attained, it becomes easy to recognise, by comparison, the moment when the two hues are alike, and, in reckoning the number of seconds required to obtain this identity, we have in this manner a means sufficiently exact to appreciate the degree of chemical action in the light at any given moment.

In the application of this instrument to photography, in order to fix the time of exposure necessary to obtain a good proof, all the other conditions being fulfilled, we must determine the relation existing between the number of seconds indicated by the photometer and that recognised as necessary to properly impress the prepared surface in the camera, whether it be silvered plate, paper, or collodion. This relation being known will serve as a rule for all the proofs which follow, whatever be the intensity of the light. It is scarcely necessary to observe that we can admit only such proofs as are made in the same conditions, that is to say, with the same objective, the same photogenic preparation, and with the same distance between the objective and the object to be reproduced.

It is indispensable that only a newly-prepared and quite dry paper should be employed; if humid, it acquires in the light a reddish hue, which will not exactly agree with the fixed hue, and after being prepared several days it will acquire a yellow colour which is equally inconvenient. However, in making use of M. Marion's boxes for keeping paper dry in, we can use it after being kept a month, without any apparent modification in its colour or sensibility.

The only source of serious irregularity we can encounter in using the photometer consists in the preparation of the positive paper. We must therefore take the greatest possible care in its preparation, which presents no real difficulties. It may readily be conceived that by employing solutions of different degrees of strength we shall have very different results as to hue and sensibility. We should therefore lay in a good stock of paper, a ream, for instance, so as not soon to require a fresh supply, and it must be unglazed. The solutions of chloride of ammonium, and nitrate of silver, should also, for the same reason, be prepared in sufficient quantity. The following are the formulæ we have adopted:—

1. Bath of Chloride of Ammonium.

Filtered Water	100 parts.
Chloride of Ammonium	10

2. Nitrate of Silver Bath.

Distilled Water	100 parts.
Nitrate of Silver	15 "

Leave the paper for five minutes in contact with each of these solutions.

Whole sheets of paper would be too expensive to prepare; we therefore divide each sheet into four, or even eight parts. For quarter sheets the bath should contain at least a quart of solution, and for eighth sheets one-half that quantity. During the time this bath is employed for the photometric preparation it must not be employed for any other purpose. There are two little cylinders of the photometer for rolling the sensitive paper upon, previously divided into little bands of an inch in width, and to make it slide before the circular opening made in the centre of the fixed hue; but when we have to make several experiments, it will be preferable to divide the band of paper into little squares, which will be placed in the little box which accompanies the apparatus.

The preserving boxes for the paper (Marion's) must be selected without any addition of chloride of lime, as this substance, by the chlorine it gives off, removes from the paper a great part of its sensibility.

The sensitive hue appears more or less deep, according to the angle under which it is viewed. It is necessary, therefore, to place it always in the same direction, which is rendered easy by the aid of a small frame furnished with a screw, the intersection of which must correspond with the centre of the disc. The photometer must, also, always be placed vertically, and in such manner that its sensitive surface be parallel to the side from whence the light, or most of the light, proceeds. When the state of the sky varies at every moment, and consequently the light also, it will be useful to operate with the camera at the same time that we estimate the duration of the exposure necessary to the proof. The following are the means to be employed:—To prove that the time of exposure must be less than that indicated by the photometer, we bring the latter to the side from whence the light proceeds, and we may discover by a few trials, the point at which the two operations require the same amount of exposure. This point is the same for all the other proofs made under the same conditions, a greater reduction of the model, the employment of a more rapid objective, or of a more sensitive preparation, naturally necessitate new trials.—*Bulletin de la Société Française.*

Scientific Gossip.

THE NEW FIXING AGENT.—PREPARATION OF SULPHOCYANIDES.—ORGANIC AND SALINE IMPURITIES IN RAIN WATER.

THE days of hyposulphite of soda seem to be numbered. A safer and, we think, better fixing agent is rapidly rising in scientific opinion, and there is every probability that it will, before many weeks are over, be introduced into the market at a price which will admit of its being experimentally tested on a large scale. Sulphocyanide of ammonium, the coming salt which is to regenerate photographic printing, and cause a faded positive to be unknown except as a thing of the past, is now attracting the attention of many large chemical manufacturers, one of whom is now erecting the necessary plant to enable him to turn out upwards of a ton a week of the perfectly pure crystallized salt; the wholesale price of which, in quantity, will not much exceed a shilling or fifteen-pence a pound. The process of manufacture we are not yet at liberty to divulge; but we have had it thoroughly explained by the manufacturer himself, and we feel justified in stating that it is one of the most beautiful applications of chemical science to the utilisation of waste products. The chemical reactions involved in the manufacture are very definite, and perfectly accomplish the desired result. We have also been favoured with samples of the product. It is beautifully white and crystalline, and contains no appreciable trace of impurity. The original source of the cyanide of ammonium is the thick tarry liquid remaining after the separation of the free ammonia from gas liquor; this has long been known to contain large quantities of sulphocyanide of ammonium, but, hitherto, all attempts to separate it from the impurities which accompany it have failed.

It is somewhat remarkable that the fixing agents already in use, hyposulphite of soda and cyanide of potassium, should be closely related chemically to the new agent sulphocyanide of ammonium. By heating together cyanide of potassium and hyposulphite of soda, the latter fuses in its water of crystallization, and remains liquid until all the water is driven off, the cyanide meanwhile remaining unacted upon; when, however, the hyposulphite is completely dehydrated, reciprocal decomposition of both salts takes place; the mass becomes somewhat brown, a little decomposition and loss of cyanogen occurs, but the greater part of the cyanogen unites with the sulphur to form sulpho-

cyanogen, which, combining with the soda present, forms sulphocyanide of sodium. In order to obtain the best result, the heat has to be attended to somewhat carefully, for, if too great, the sulphocyanogen itself is decomposed, whilst if, on the contrary, it is not sufficient, proper decomposition of the hyposulphite does not take place. After the fused mass is allowed to cool, it may be powdered and heated with alcohol; this extracts the sulphocyanide of sodium; probably a slight modification of the process, and the introduction of a salt of ammonia, would enable pure sulphocyanide of ammonium to be formed directly; but the process in any case is only of scientific interest, as showing the great relationship existing between the old and new fixing agents, for the expense would be very considerable.

The expensive cyanide of potassium may be replaced by the cheaper ferro-cyanide of potassium. Upon heating this with hyposulphite of soda, a somewhat similar decomposition takes place to the one mentioned above; and upon this reaction a very easy method of preparing sulphocyanide of sodium or potassium has been devised. One part of ferro-cyanide of potassium, and three and a half parts of hyposulphite of soda, are well dried and mixed together. The mixture is heated in a porcelain dish until the hyposulphurous acid is decomposed. The sulphocyanide is extracted at once from the doughy mass, by means of hot alcohol; or the mass may be left to cool, then treated with boiling water, and the sulphocyanide separated by crystallization. Sulphocyanide of potassium may be prepared in a similar manner, by fusing one part of dried ferro-cyanide of potassium with three parts of dried hyposulphite of potash.

We have on many occasions urged the necessity of photographers who use rain water testing it for organic matter, before use, by means of a weak solution of permanganate of potash, which will be discoloured unless the water be perfectly free from this impurity. The subject of rain water has recently been examined with great care by M. Robinet. He has collected and examined the water falling in Paris, during the last eighteen months, having made a hundred and eighteen observations. He found the water always more or less charged with saline matter, the larger quantities always being found after prolonged drought. On collecting the water during continued rain he found that the amount of fixed matters diminished as the rain continued; showing that the saline impurities were derived from the atmosphere, and from the road-dust accumulating upon the roof in dry weather. The saline matter was principally sulphate of lime, always accompanied by a little organic matter. The amount of sulphate of lime is sometimes rather considerable. The organic matter present is not thoroughly understood, it causes the rain water to froth on agitation more than any water which M. Robinet compared with it. On adding a solution of nitrate of silver to the rain water, various shades of red were in time produced, forming, on standing, a reddish deposit which contained silver. The exact nature of the substance which produces this colouration is not yet known, but it will be the subject of future experiment. It has long been known that rain water contains organic matter, and it has been assumed that the presence of this organic matter must necessarily be injurious to photographic processes in which it is introduced. Here, however, we have a positive confirmation of the accuracy of these surmises, showing more forcibly than anything we can say, the necessity of only employing rain water which has either been proved to be free from organic matter, or which has been purified from it by permanganic acid, in the manner described in these pages some few weeks ago.

PHOTOGRAPHIC PRINTING AND ENGRAVING.

BY WILLIAM CROOKES, F.R.S.*

THE uncertainty which is a necessary accompaniment of the ordinary method of photographic printing, its great expense, the extreme difficulty of producing a sufficient number of presentable pictures of the same subject to satisfy the requirements of book-illustration, and the utter impossibility, in the present state of our knowledge, of procuring a photographic print which can be relied upon for permanency, have caused men of science to turn their attention, from the earliest days of photography, to the problem of causing the photograph to impress a metal plate or lithographic stone, in such a manner that the subsequent copies could be struck off in printer's ink.

A somewhat similar problem, but one of far less utility, has been to produce photographic prints on paper, prepared in such a manner that the dark portions of the image should be composed of carbon, or some other body of which it can confidently be asserted that no ordinary atmospheric influences would cause it to change. This latter problem has been followed up with some ingenuity by many experimentalists, both in England and on the Continent; but as they are all open to the grave objection that the mechanical operation of printing is as slow and uncertain as the ordinary process, they need not be further alluded to.

Passing rapidly over the first rude attempts of Donné, Niéce, Berres, Fizeau, Nègre, and perhaps some others, none of which met with much success, we come to the photographic process of Talbot, the basis of which was first published in the early part of 1833. The principle which he adopted was an entirely new one in that branch of the art: it may be briefly explained as follows:—A solution of gelatine or isinglass, containing a little bichromate of potash, is poured on to a steel plate and allowed to dry. If one-half of the plate is covered with a piece of card so as to obstruct all light from it, and the other half exposed to the action of sunshine for a minute or two, it will be found, on examining the plate in a dark room by the light of a candle, that the portion which has been exposed to the sun has become of a brown colour, whilst the shaded part of the plate remains of the original yellow tint. This is a well-known photographic property of bichromate of potash, and was long before applied by Mr. Ponton to the purpose of printing photographs on paper. But, besides a change of colour, another alteration will be found to have taken place. If dipped into water, the gelatine and bichromate of potash which has not been acted upon by the light will gradually dissolve, and leave the steel surface quite clean; but the other portion which has been turned brown by exposure to the sun's rays will scarcely dissolve at all. If, instead of a piece of card, the leaf of a fern, a piece of lace, or the light feathery flower of a grass, is pressed in contact with the prepared surface of steel by means of a thick piece of plate-glass, the finest line, and even the minutest fibre or thread, will be copied on to the steel surface, and, after being washed with water, will show an eminently beautiful white image impressed upon a yellowish-brown ground. The next step in the process consists in etching this steel plate in such a manner that an impression of the object can be struck off in printing ink. This is a matter of more difficulty than would at first sight be imagined; many chemical agents are known capable of attacking the exposed surface of the steel plate, whilst they will have no action on the parts protected by the altered gelatine, but a plate so etched will not give a good impression, except under very favourable circumstances. If the negative has been a piece of black lace, the finished and etched plate will have a perfect representation of the lace

PHOTOGRAPHY AND THE SOCIAL SCIENCE CONGRESS.—We understand that MM. Edmund Potonie and Radoult, of the *Comptoir International des Photographes*, are about to publish photographic portraits of the members of International Social Science Congress. They will be published simultaneously at the offices of the Comptoir in London, Paris, and Bruxolles.

* *Popular Science Review*. This interesting article, by Mr. Crookes, is illustrated by a photolithographic copy of a page of the *Times*, in a space of 3 inches. It has been photolithographed by Messrs. Kider and Preston—the first-mentioned gentleman having been one of those engaged in connection with Colonel James, in the Ordnance Map Office, at Southampton.

eaten into its surface, to a considerable depth, by the action of the corrosive liquid, and if this be given into the hands of a copper-plate printer, he will, in all probability, produce very beautiful and perfect prints, which at a little distance could not be distinguished from the original lace.

The perfection of this kind of subject is due to the lines of etching formed by the threads of lace being of such a diameter that the ink is properly held by them; but if, instead of a piece of lace, a photographic picture were used, a very different result would be obtained. The steel plate, it is true, would be impressed with an exquisitely beautiful image, and upon applying the etching liquid, the picture would be bitten in with tolerable accuracy; but when tested by the printing press, the plate would be found sadly deficient. A careful examination will show where the fault lies. Where the light has acted strongly the plate is not etched at all; where the light has not acted, the plate will be corroded very deeply, and if this portion represents fine lines, such as the branches of a tree, or a row of palisades, the ink will be held by them, and produce a good print; but, if a surface of the plate is etched in this manner, there will be no means of holding the ink, and that portion will not, therefore, give an impression. Again, a half-tint will be represented on the plate by an uniform corrosion of the surface to a slight depth; but, for printing purposes, half-tints of various degrees are required to be represented by lines or dots of different distances apart.

This difficulty besets all processes for photographic engraving; pure black and white can be given easily enough, but the half-tints, which constitute nine-tenths of a good photograph, have puzzled many experimenters to master. Talbot partially overcomes this difficulty, by producing an artificial aqua-tint ground on the plate, either by impressing it with the image of two thicknesses of black lace crossed diagonally, or by spreading very evenly over the surface of the plate a little finely-powdered gum copal, and then, treating it in this manner, the ink is enabled to adhere to those portions which constitute the half-tones of a picture; and by adopting either of these artifices, the photoglyphic process, as Mr. Talbot terms it, has yielded results which, in the hands of a skilled operator, and on small plates, can scarcely be surpassed.

The photogalvanographic process of Pretsch is somewhat similar in the commencement to the one just described. A plate of glass, or any other smooth surface, is coated with bichromate of potash and gelatine, and then exposed to the light under a photograph or an engraving; it is then moistened with water, but not thoroughly washed. The first action of moisture is to cause those portions of the surface which have not been exposed to the light to swell and rise up, more or less, in ridges from the surface of the plate. A mould is then taken from the plate so raised; from that an electrotyped copper plate is procured, which is used as a matrix, from which other plates may be produced suitable for printing purposes. The gelatine, in swelling, is found to split up into ridges, giving to the whole surface a granular effect, which holds the printing ink equally well in the fine lines and the broad masses of shadow. This process gives very effective prints when they are large, and viewed from a distance; but for fine, delicate work it is not so successful.

Another process has been brought to considerable perfection, by Sir Henry James, in the Ordnance Office, Southampton, where it is used for producing copies of maps. A mixture of gelatine and bichromate of potash is in this case also the foundation. A surface prepared with this mixture is exposed to the action of light behind a transparent picture of the map, or other object to be copied, which is tightly pressed against it. The change which has been already described takes place, and now a roller charged with lithographic ink is passed over its surface. This blackens the whole, but when it is soaked in warm water, those portions of the sensitive surface which remain unchanged by the action of the light are dissolved out, and

the lithographic ink is thereby removed from those parts of the picture. A prepared flat surface of zinc is then placed in contact with the inked picture, and the two are submitted to heavy pressure, when a complete transfer of the picture will be found on the zinc. After suitable preparation any number of copies can be printed from this zinc plate in the ordinary printing ink. This process is capable of giving very perfect results, and when applied to the reproduction of manuscripts, prints, or similar matter, it is impossible to conceive a more perfect reproduction. Indeed, it is no easy matter, when the original and the photogalvanographic copy are placed side by side, to distinguish one from the other; and if the copy has been reduced in size by the photographic means, most persons would prefer it to the original both in point of delicacy and sharpness.*

The last process with which it is necessary to treat, is the invention of Mr. Dallas. No explanatory details are given by the inventor, but there is little doubt, from the results already exhibited, that it is a modification of one or both of the photoglyphic and galvanographic processes. The great difficulty has always been to retain the half-tones. Mr. Talbot's process, it is true, solved this most perfectly. Before us is a print representing a portion of the palace of the Tuileries. The richness of the sculpture, the number of the statues, and the numerous fluted columns render this an exceedingly difficult subject to engrave by a chemical process, owing to the great variety of tints which it represents; and it affords ample evidence that this kind of photoglyphic engraving is capable of rendering the most delicate gradations of tone, and the accurate delineation of details as perfectly as the bolder outlines of the picture. Confining the scrutiny to certain portions of the picture, the effect is quite equal to any photograph printed in the ordinary way, which is giving it the highest possible praise; but when the picture is viewed as a whole, it appears patchy and unevenly developed. Owing to the difficulty of overcoming this defect, photoglyphy is now but very little heard of. Mr. Dallas seems in a great measure to have succeeded in overcoming this want of evenness, and has produced pictures which, regarded as a whole, must be considered very satisfactory specimens. They will not bear microscopic examination, as do many of Fox Talbot's, but, as pictures, they are much superior to any untouched specimens produced by either of the processes alluded to.

An art like this is still in its infancy. As soon as a method of photographic engraving comes into general use for book-illustration, improvements will follow one another rapidly; the faults above pointed out are, in a great measure, due to inexperience or defective manipulation, and would vanish as soon as a demand arose amongst the public for such illustrations. The general adoption of a process of this kind would be invaluable; an engraving of any object or scene, however good the artist might be, is not, and cannot be, an exact representation; at the best it is but a mere approximation to that, and there is always a tendency for the artist to idealise the subject and render it difficult to recognise at first glance, or he will not descend to those minutiae of detail which give such a charm to the photograph. The great value of photography is that it produces absolute *fac-similes*; but this value is lessened by the tedious rate of reproduction, and the great probability that in twenty years' time upwards of ninety per cent., of the photographic prints now in existence will have faded out. By wedding engraving to photography, and making the same physical agencies which impress the sensitive tablet produce the engraved plate, the mathematical accuracy of form and detail possessed by the photograph is secured, united to the permanence of a printed book.

For the illustration of objects of natural history, flowers, plants, and animals, even to the most minute microscopic

* Mr. Crookes appears to have overlooked the labours of Mr. Osborne, one of the most energetic and able of photolithographic discoverers.

object, this invention is invaluable. By its means *fac-similes* of rare engravings or manuscripts are even now, as in the case of "Doomsday Book," multiplied to any extent, and circulated amongst the public at a price which formerly would not have been paid for the commonest woodcut.

CARBON PRINTS ON PLAIN PAPER.

MR. WILLIAM BLAIR, of Perth, to whom, as we recently intimated, the original idea of obtaining half-tone in carbon photographs, by printing through the paper, is due, has described, in the *Photographic Notes*, a new method of obtaining carbon prints on plain paper. After some preliminary remarks congratulating Mr. Pouney on his results, he remarks that he is still convinced, however, that all prints upon oiled, or waxed, or varnished paper, will have many disadvantages. He adds:—

"They lack the freshness and vivacity of prints on plain white paper—there is a difficulty in mounting them properly—and they cannot be easily tinted in water colours. I therefore believe that many will prefer to work the simpler processes which I am now about to explain."

He then proceeds with his own process as follows:—

"First, Take a sheet of good white homogeneous paper, softly sized, and as smooth as possible on the surface—I have found some specimens of well-pressed common scroll paper answer wonderfully well; gelatinize the smoothest side by floating for a minute or so on a dish of diluted warm gelatine, mixed with a little common salt. If the dish has a smooth level edge, draw the gelatinized side of the paper over the edge with a slow, regular motion, or over a smooth fixed roller conveniently attached, so as the better to equalize the gelatine, and carry away air bubbles, which must always be got rid of. Then hang it up to dry, or throw it on its back and let it dry, in a place protected from dust. This should be done with a large number of sheets successively, so as to use up the gelatine while it is fresh and in good condition.

"Second, Take a quantity of albumen and put into it a very small quantity of syrup and a very little water. Then consider what tone or colour you would like your prints to assume in the middle shades. If landscapes, perhaps a blue tone would please (and blue at this stage has an advantage which I will afterwards refer to), in that case take a cake of Prussian blue or indigo, or if you wish a warm tone, say for a building or a portrait, take red lake, or burnt sienna, or any fine *transparent* water colour, or mixture of colours you please; or if a plain black is desired, use fine china ink, and rub or grind this down among your albumen in such quantity that, when spread on paper with a brush, it will give a good depth of half or middle tone. Beat the whole to a froth, and let stand till the albumen settles, then pour off into a small bottle for use.

"Third, Obtain or prepare very fine dry carbon, free from grit or oiliness, and keep it for use in a wide-mouthed phial. It may be mixed with burnt sienna, very finely ground, or any other permanent semi-transparent colour which has not a metallic base, if you wish to modify the tone of the carbon.

"Now proceed with the preparation of your paper as follows:—

"Take one of the gelatinized sheets, lay it on its back for a few seconds on the surface of a dish of water (gelatine side upwards) till it lie flat, then take it up by two corners, let it drain for a moment, or place it back down on blotting-paper, previously damped and pressed, to liek up the superfluous moisture; then lay it, back still down, on a sheet of dry glass, somewhat larger than the paper, and pour about as much of the coloured albumen upon the paper as can be spread thinly over the whole surface of the gelatine, with a soft camel-hair brush, and spread it accordingly. Don't mind though part should get frothy, the next operation will clear that away. Then take a large broad soft hog's-hair brush and sweep very gently in all directions, so as to carry

off from the surface, over the margin, all superfluous matter, taking care not to press so heavily as to disturb seriously the gelatine beneath; leave off before the surface has dried to tackiness. The sheet should then present a fine uniform transparent surface in half shade when viewed by reflection, but when viewed by transmitted light, should appear very little darkened by the colouring matter. Take care of dust in the brushes, or from any other source. Lay the paper aside to dry, and treat the whole batch in the same way.

"You may have albumen of different tints, so as to get any desired variety of tone in the same batch of paper.

"Both after gelatinizing and albumenizing, it is convenient to put the paper, when dry, into a blad or large book, that it may assume sufficient flatness to be easily handled, and spread again on a dish of water without air bubbles.

"Next comes the carbonizing; and this, though simple and easily managed after a little practice, requires some care, and even expertness in certain conditions of the paper, to get an even coating. The paper must be damped on the back, but the secret is to take care that it is not *too* damp when the carbon is laid on.

"Take a sheet of your tinted paper, lay it carefully, back downwards, on water for a few seconds, avoiding air bubbles. Quickly lift the one end half out of the water, and then the other, dispersing any air bubbles with a brush—if not quickly dispersed, they will cause blank or whitish spots on the upper surface afterwards—then lift the sheet off the water, lay it down on damped blotting paper, previously pressed level, or on glass, back still down, and with a sheet of dry blotting paper above, level it well down, so that the moisture on the back will be equalized. This must all be done quickly, the success of the carbonizing depending much on it. Then pour a quantity of dry carbon on the surface of your paper in a small heap, and with a large, soft camel-hair brush, thoroughly dry, distribute the carbon very quickly over the whole surface, leaving about half an inch of margin all round untouched, in case of the brush coming in contact with any water that may have come round the edges from the back. Brush all the carbon that does not adhere to the surface towards the one end, in a small heap, and return it to the bottle, then continue for a short time brushing gently in all directions, so as to drive the carbon slightly into the albumen, and sweep away with the brush all that is not adhering to the paper. If this is properly done, a fine uniform semi-transparent surface should be presented, and yet of sufficient density to form the darkest shades necessary in a picture. By holding up the paper and looking through it against the light, you will at once be able to judge of its fineness and uniformity, and if it is not quite uniform and semi-transparent, but clouded with dark spots, endeavour to manage the next sheet better. This is a mere matter of mechanical dexterity, but on which the fineness of the ultimate result greatly depends.

"What I have now explained is the most troublesome part of the process, but in reality it is simpler than at first sight it would seem from the above minute mention of particulars. Fortunately, all this can be done in broad daylight, and what I wish to call particular attention to, is that up to this stage the paper could be prepared and sold by manufacturers, ready for use, just as collodion or albumenized paper, and other photographic materials, are prepared and sold at present. Had every one to prepare his own collodion, it would probably deter me and many others from attempting the use of it.

"The next stage is the sensitizing. This is very simple. Have a saturated bath of bichromate of potass, about two parts water, and one part common commercial acetic acid—the acid makes the bath penetrate the paper more quickly. Lay a prepared sheet, back down, on the surface of this bath (in the dark room, of course), avoiding air bubbles as before. Allow it to float for half an hour or an hour, according to the quality of the paper, till the bichromate has well penetrated to the upper carbonized surface, but not till the paper is soaked. The paper should be least sensitive on the car-

bonized surface, and increased in sensitiveness internally towards the back, inversely to the action of the light, as afterwards explained. Then hang up to dry in the dark.

"EXPOSE.—Lay your paper in the pressure frame, with its black or carbonized surface next the negative film, and expose in the usual way in good sunshine. Sunshine is not absolutely necessary, especially with weak negatives, but as a rule I think it is best, from its power of penetrating the paper, and more easy calculation of the proper time. In sunshine you will require to expose from five to twenty minutes, according to the density of your negative. Your negative should be as dense as to require about ten minutes at least. When examined on removal, a very decided impression should be seen by looking through the paper, not of course visible in the finer details, otherwise it is probably over-exposed, and will be troublesome in the washing up.

"WASHING.—Begin with cold water, and let steep for a short time, say twenty or thirty minutes, then come over the surface gently with a broad soft brush. If the carbon does not appear to yield any in the high lights, pour in a little warm water and try again with the brush, and so on, increasing the heat of the water to a moderate extent, and trying the brush. If rightly exposed, the picture should gradually clear up under the softening of the water, and the gentle friction of the brush. The brush should not be used with any violence, but simply to remove more speedily what the water has already softened or dissolved. Sometimes, indeed, when the picture has been over-exposed, I have used the brush with considerable pressure, and even a sponge in some parts, without spoiling the picture; but as a rule violent rubbing is incompatible with obtaining the finer half shades.

"A little acetic acid or liqueur ammonia, mixed with the water, will facilitate the dissolving of the albumen and clearing up of the picture, when there is any great delay from over-exposure. The last washing should be in clean water, and the picture is then dried. If any of the details are lost in the washing through under-exposure, or too violent rubbing with the brush, the picture may still form a good groundwork for water colours.

"Paper prepared as above directed, will, before sensitizing, keep for any length of time; also after sensitizing it will keep for a considerable time, and yet produce tolerable pictures; but I am of opinion that the quality of the picture depends a good deal on the exposure and washing being carried through within a moderate time after sensitizing. Indeed, I am inclined to think that for the best pictures the paper should not be allowed to become *bone dry* before exposure, as the bichromate has then a tendency to crystallize and produce a granular effect; but the syrup mixed with the albumen has a tendency to retard this result, and give greater latitude. The syrup, also, besides rendering the albumen more tacky to attach the dry carbon at that stage of the process, makes it afterwards more easily dissolved in washing up the picture, and it is important, as will afterwards be seen, that the carbonized surface which is exposed to the greatest light should be more soluble than the gelatine beneath, which is to support the half-shades.

"The salt in the gelatine disposes it to absorb moisture quicker from the back of the paper, during the different operations above described.

"The sensitizing the paper from the back is convenient, as it does not disturb the carbonized surface, which would easily be washed off. But it is important in another respect which has already been indicated, but which will appear more plainly on now considering how far the above process is right in theory.

"In January, 1859, I first announced through the *Notes* the result of my printing in carbon on plain paper by placing the back of the sheet against the negative, and this was considered an improvement at the time, though its importance was not fully recognized, and I had not a sufficiently transparent medium to do justice to the carbon. I afterwards tried waxed paper however, and was further satis-

fied that the theory I had formed was correct, as the granulation was considerably reduced. In 1861, I recognized the same principle as being involved in M. Fargier's plan of printing on the black surface, and preserving that surface by transference to another sheet; and I wrote a letter in defence of his plan, and of my own, which was published in No. 117 of the *Notes*. In that letter I stated pretty fully my views on the subject, maintaining that the different gradations of shade arose from the different depths that the light penetrated into the carbon; that the true picture, as thus hardened and fixed, was always on the sunned side, and that that side should be preserved. This is now acknowledged to be sound, and Mr. Poncey is acting upon that plan.

"Well then, it may perhaps, at the first glance, be thought that the method of printing which I am now recommending is at variance with the above theory, but it is not so. It is founded on the recognition of that very theory, and deviates from it as little as circumstances will permit. It is true the exposure is reversed; the negative is placed direct against the carbon surface, and the carbon surface first receives the light, and that surface is not entirely preserved, but is in part washed away in getting at the picture. But just because the process is thus far reversed, I have endeavoured to meet this reversal by a series of compensations, the working of which will be understood on a little consideration. In the first place, the carbon coating is laid on so thin as to remain very transparent, and thus to interrupt as little as possible, especially in direct sunshine, the passage of the light to the interior of the paper. In the second place, I have recommended a transparent *blue* colour below the carbon, as being more actinic and easily impressed with the little light that reaches that region. In the third place, I have placed gelatine next the paper, and mixed albumen and syrup next the surface, the latter being comparatively more easily dissolved in cold or lukewarm water than the former, which is the support of the finer half-shades. And, fourthly, I have sensitized from the back of the paper, so that it is a mere filtering of the bichromate that reaches the carbon surface, and the sheet thus prepared is not so sensitive on the carbon surface, which receives most light, as it is in the interior, which receives comparatively little light, thus compensating by sensitiveness for the weakening of the light as it reaches the material which is to form the half-shade. By this arrangement the interior is hardened about as speedily as the surface, and the result is much the same as if no blackening were on the surface, but the whole sheet equally transparent and equally sensitive, in which case it would evidently be immaterial which side is exposed to the light. Such appears to me to be the extent to which this process is right in theory, and it is corroborated, I think, by the results I have obtained.

A FEW THOUGHTS ABOUT PHOTOGRAPHIC SOCIETIES.

AN OPENING ADDRESS, BY ALFRED H. WALL, HON. SEC., S.L.P.S.*

I HAD been looking thoughtfully over the reports of the various photographic societies, when it struck me that institutions exercising so important an influence upon the wellbeing and progress of the photographic art-science, ought themselves to be a matter of earnest consideration. As this, the first evening of our new session, drew near, I began in the performance of my duty, as secretary, to cast about for some one or more good and interesting papers to be read thereat, and finding it difficult to procure them in time for that occasion, resolved that I would myself prepare a paper, taking for my subject such societies as we now represent. As I am going to speak very honestly some of the thoughts I entertain on such a subject, I must begin by requesting you to remember that I shall speak of such

* Read at the South London Photographic Society, on Thursday, Oct. 8th.

societies generally, and have no intention of particularising either this one or that.

Photographic Societies are not readily appreciated by strangers. Their aspects are so various, that it is only by frequent visits to their ordinary meetings that you can understand them. The range of subjects which comes under attention for discussion thereat are such as, until the introduction of photography, were seldom associated together. The rules of art, the laws of chemistry, the principles of optics, and the secrets of certain mechanical crafts, seem in the non-photographic mind to possess so little in common, that strangers wonder when they hear each, or all, of these dissimilar subjects blending in a discussion following some paper on one or other of the processes of photography. This is very apparent in glancing over the reports of such societies in the photographic journals. Now they appear like societies of fine art students, enthusiastically dwelling upon æsthetics; and anon you could imagine them congregations of unpretending cabinet-makers, every man with a six foot rule in his trousers-pocket, and a big square lead pencil in that of his waistcoat. Again they show like learned chemists, investigating the hidden mysteries of nature, and reducing to their elements every component portion thereof; and yet again they show like grave opticians, ready at the shortest notice to chalk you in white lines upon a black board any number of eye-confusing diagrams, which, to the uninitiated, shall resemble nothing but the ramifications of a spider's web, or the intersecting routes of all the various railways in the three countries of England, Scotland, and Ireland.

In consequence of this blending of seemingly inharmonious elements, photographic societies are, or should be, composed of photographic artists, chemists, opticians, mechanics, and operators; the latter title, in some cases—so accomplished are many photographers—comprising, perhaps, all the others; and from this fact arise certain features peculiar to such societies, some of which are admirable, and others of which are—well—not altogether so. The former being represented by the benefit which always ensues from the bringing together, and comparing of views taken from different stand points, and the latter arising from the exposition of crude ideas on subjects in which certain members may be deeply interested, but in which they are certainly not deeply learned. In this case, of course, the good and its reverse must be taken as we take light and shadow in nature; only for the sake of the public reputation of such societies, it would be well if their reports should either be drawn up by such accomplished gentlemen as are tolerably well informed on all these subjects, or submitted previous to publication to a competent and fairly representative committee of the society concerned.

I next, rather hesitatingly, venture upon some few remarks on another peculiarity of photographic societies. It is a peculiarity with which, as readers of the photographic journals, we are, unfortunately, not unfamiliar.

It is no very difficult thing to join a photographic society. You have but to send your card to a member, or to the secretary, or to the editor of your favourite photographic journal, and the thing is done. It is not asked that you shall have attained any fame in any particular branch of art or science associated with or having a bearing upon photography. It is not required that you should be a photographer, either amateur or professional. You are elected to the tunes of "the more the merrier," and "no questions asked." Being elected, you speak at the society's meetings, and afterwards read your name and utterances in neat black print, conscious the while that your words are travelling into foreign lands, and that your name will be seen of men afar off. So it sometimes happens that members who have nothing to say, and are very ambitious of saying it, write it out at great length in more or less elaborate papers, which they are kind enough to read before our photographic societies. That every now and then a gentleman who has mysteriously and suddenly become deeply scientific, instead of seeking distinction in other quarters,

brings forward his startling and very original theories for the enlightenment of photographic societies, and that youthful photographic aspirants come confidently forward at their meetings to describe at length full-length feats of skill only to be equalled by that of the undying Homer—

"He who with philosophic eye
Sat brooding o'er his Christmas pie,
Then, firm resolved, with either thumb
Tore forth the crust-enveloped plum,
And, mad with youthful dreams of future fame,
Proclaimed the deathless glories of his name!"

The evil of all this is, that it gives the enemies of our societies the means of ridiculing them; that, by lowering their tone, it makes men of really high attainments in art and science hesitate about joining them, and that it thus operates against the permanent usefulness of such societies, by excluding elements upon which they are dependent for thoroughness and stability.

To meet this difficulty it is only necessary that the officers of a society should insist upon receiving the MS. of all papers proposed to be read before such society at least a fortnight previous to the night of meeting.* Of course, this could not be done without the co-operation of the members generally. Of course, also, there are contributors of papers whose names would sufficiently guarantee the character of any communications they might feel inclined to honour a society with; but these gentlemen being generally only too desirous of benefiting and elevating the art-science, would surely not refuse compliance with a rule intended for such an end, it being obvious that to avoid an appearance of anything invidious the rule must be applied to all.

Among other advantages which this rule would ensure, would not only be the raising of the character of a society's proceedings, but the certainty which its members would feel, accidents notwithstanding, of always finding a paper, or some other interesting subjects of discussion, prepared for them,† and the consequent increased regularity of their attendance. Under the regulations, or, rather, want of regulations, now adopted, the members of these societies frequently come through inclement weather many miles from home, only to find a bare, empty, comfortless meeting, and a chairman full of regret to say that no paper had been provided.

One of the most legitimate means of encouraging and propagating a spirit of enterprise and improvement has been found in awarding honorary distinctions, such as medals, for excellence of production. I think several of our photographic societies have done well in recognizing this, and I would recommend the adoption of this practice to such as have not yet adopted it.‡ It was one of the first means by which the Society of Arts did us so much service by initiating a new era of progress in all the arts, the fine arts not excepted. But in making such awards, the most scrupulous care should be taken to secure the doing of impartial justice, as upon this the real value of all such distinctions must be dependent. Every quality for which these awards are to be made should be of a lofty character, and be decided upon by judges professionally familiar with its best characteristics. The prize productions should, of course, in every case be publicly exhibited. Those who are inclined to dispute the policy or tangible good effected by these rewards, are recommended to read Mr. Aiken's address, delivered to the members of the Society of Arts, on the 12th of May, 1829, at the close of which is given a long list of the eminent artists who had competed for and won the medals which, great and celebrated as they became, they were always proud of possessing. Such of the societies

* Or, better still, if practicable, to adopt the plan of the Glasgow society, and announce at the commencement of the session the papers to be read on each of its forthcoming meetings.

† If the committee had a fortnight's warning of a paper not being forthcoming, they could fall back upon their own resources, which might be withheld for such occasions, or, at least, take steps of some kind to bridge over the difficulty.

‡ The first expense incurred in producing a medal is, of course, considerable, and the practice could, therefore, scarcely fall within the reach of our less prosperous, although, by no means, least useful, societies.

as distribute photographs of great merit amongst their members might associate, with the choice of their presentation prints, the competing for medals to be awarded to the producers whose pictures were chosen.

The first thing necessary for the encouragement and advancement of art in all its branches is, that a love and appreciation of it should be created in the public mind. To this end, long experience seems to show that there is no medium better than public exhibitions.

David Hume tells us that a state can scarcely carry its trade and industry very far, where all the surrounding states are buried in ignorance thereof, and this fact has its application to every branch of commerce of every kind. It is public patronage which develops and encourages every branch of art. Public patronage is only another name for public appreciation, and public appreciation cannot exist without the means of appreciating, or, in other words, of educating the public taste, for which purpose, it is well understood, no medium surpasses in importance that of exhibitions. This has been generally recognised in photographic societies, and every lover of the art-science—photography—should, therefore, eagerly and cheerfully co-operate to make these exhibitions thoroughly successful. The amateur or simple lover of the art, should strive to produce his best picture for this end. The professional should send his most artistic, attractive, and interesting specimens, and as these exhibitions have their origin in our photographic societies, photographers should consider aiding in the support and permanent establishment of such societies as a positive duty.

In proportion to the importance of our exhibitions should be the care and thoughtfulness expended in their management. Their managers should remember, as a recent writer in the *Times* said—"That motives of self interest sway the bulk of mankind, and that it is necessary to take these into calculation if you wish to influence the action of numbers." They should aim to bring together not only such specimens of the art's best productions, as photographers and artists will appreciate, but such as may also legitimately attract and please the general public. The exhibition of a monotonous collection of uninteresting subjects, although they may yet serve to illustrate to the full all the beauties and perfections of photographic operations, and win high praise from those who themselves practise and understand photography, will neither do much to advance the art in public estimation, nor encourage the exhibitors by increasing the number of their patrons. Not that I would advocate the sacrificing of excellence of production for attractiveness of subject, be it remembered. This would be too great a price even for success. Of course, every encouragement should be held out to attract exhibitors, because the larger their number the more various and numerous the specimens from which to select for exposition, and, judicious selection being pre-supposed, the greater the resulting attractiveness of the exhibitions. When exhibitions are successful, the societies to which they belong should gratefully remember that such success is due to the labours and talents of the exhibitors, and when they are not altogether successful they should still regard any pecuniary loss which might follow as money legitimately expended.* I should not consider it sound policy to ask exhibitors who are not members to contribute in making up a possible loss of this kind by paying for exhibiting space, however small the charges made might be. The speculation, not being that of the exhibitors, but that of the society, which, as it alone must reap the benefit of any probable success, should also be prepared to pay the cost of any probable failure, if the word failure may be strictly applicable in reference to a speculation intended rather for the encouragement and advancement of an art than the acquirement of idle revenue.

The commercial aspects of photography are so intimately associated with its improvement and prosperity, that societies

would do well not to overlook this subject. Writers on the laws of supply and demand in trade, all tell us that while scarcity generates competition amongst the buyers, and so keeps prices up, a supply exceeding the demand, sets the sellers anxiously competing, and so brings prices down. Now it seems to me, that in the most popular branch of photographic art—portraiture—we find this very aptly illustrated. Therein "cheapness is the order of the day." In the advertisement columns of the daily papers, almost every week shows us an increasing number of those photographers who are bent upon under-selling their rivals. The carte portraits, the "postage stamp" portraits, and the fifty reproduced portraits for half-a-crown, readily suggest themselves.* Establishments commanding higher prices, in vain stood out against the rage for cheapness, and one by one they have lowered their flag of high prices. Clever operators receiving high salaries, were engaged for the production of low priced pictures; and, although the rapidity with which they were compelled to do their work, "to make it pay," did not enable them to do full justice to their abilities, they certainly turned out photographs fully equal to those produced by many of the "higher priced" establishments. But the sign of cheapness is not a wholesome sign in the arts, whatever it may be in other branches of commerce. The practice of photography up to a certain point of common place merit is not difficult, the expense of apparatus, even when first class, is not great, especially when intended for the production of the small cheap photographs, and recruits are flocking into the ranks of the profession daily. Where, then, is this race of cheapness to end?

Under these circumstances, I would suggest to societies another view of this matter.

In the "fine arts," we have a certain class of productions which are so common as to sell for the most ludicrous prices. Their producers work in a state of shabbiness and semi-starvation in poverty-stricken garrets. You may picture one of these "artists" for yourselves, if you please. He is popping about, in his sky-parlour studio, from one to another of a row of canvases. With four sweeps of a brush filled with blue paint, four azure skies are completed; with the same number of dark violet streaks, four bits of distant country are created; four streaks of pale blue make four silvery rivers; and four sets, of a dozen dabs each, manufacture four green foregrounds. Four windmills are as expeditiously originated, and four picturesque cottages occupy no more time. Two or three narrow streaks of brown in each picture are then crowned with four dabs, made with a piece of sponge dipped in green paint—and lo! there are four "beautiful oil paintings," ready for the Dutch-metal "gold" frames of the cheap auctioneer or the travelling pedlar. This is what cheapness does for art, and if all our oil paintings were of no higher merit, painting would be contemptible, and these men would be our only great artists. Those acquainted with the history of art may indeed remember a time when art in this country was very little above such a level of degradation, and men of real talent were wearing out their pitifully wasted lives in the painting of tradesmen's signs and attractive pictures for the outsides of travelling fair-booths.

From the possibility of any similar state of degradation and misery, our photographic societies should anxiously guard the art they represent. There is one way of doing this, and that is by cultivating the higher aspirations of our ambitious artist-photographers, and forcing upon the public the recognition of their superior merits. Let them give more of their attention to photography as a fine art; let them cultivate not only the mechanical, but the æsthetic elements of the poetical and picturesque; and superior productions, associated with the effect of that publicity which is afforded by well organized and carefully managed exhibitions, must speedily raise the standard of excellence

* Providing always that such losses do not endanger the existence of the society.

* A friend yesterday informed me of an establishment in the city, now advertising "one hundred autograph portraits for five shillings."

into a region in which its refined and educated practitioners will be necessarily few, and its productions, as necessarily not cheap.

I have much more to say, and many more hints to give, but my paper is already too long, and lest so interminable a sermon should exhaust your patience, or I should find my hearers one by one dropping off into a comfortable nap, I will conclude. My remarks may not be looked upon with a favourable eye in every quarter, but I make them in all honesty and earnestness, being desirous only that photographic societies should see their own importance, and take such steps as may be permanently beneficial to the art and its professors, as well as to their own stability and honourable position. As Sir John Herschel says of science generally, so should it be said of photography as combined art and science, viz., that, "it delights to lay itself open to inquiry, and is not satisfied with its conclusions until it can make them broad and beaten, its whole aim being to strip away all technical mystery, and to illuminate every dark recess with a view to improve them on rational principles."

RAPID TANNIN PLATES WITH ALKALINE DEVELOPMENT.

BY THOMAS SUTTON.

MR. SUTTON has recently been trying tannin plates prepared with bromo-iodized collodion, and developed with an alkali in combination with a solution of pyrogallie acid without silver, as first proposed in the *Photographic News*. He has met with great success, which he describes in his *Notes*, from which we extract the following:—

"The alkaline development of dry plates has proved in our hands an extraordinary success, and by means of it we have rendered more than one of the slow dry processes as rapid as good wet collodion. This is certainly a very important result, and we hasten to lay the particulars of our experiments before our readers, for assuredly nothing of equal interest has occurred in photography for some time. The use of an alkaline developer for dry plates seems to us nearly certain to revolutionize the whole practice of out-of-door photography, whether for slow or instantaneous work, nor is it at all improbable that it may affect considerably the in-door operations of the photographic portraitist. There are so many advantages in a rapid dry plate, that when a good and certain process of preparing and developing such plates is generally understood, they cannot fail to be largely used in preference to wet plates.

"The mode in which we have employed an alkaline developer with so much success is simply as follows:—

"Make a saturated solution of bicarbonate of soda in cold water, and filter it. Make also an alcoholic solution of pyrogallie acid of the strength of 10 grains to the ounce of alcohol, and filter it also. Then develop in the following manner the dry plate, which has received only the same exposure as you would give to a good wet collodion plate:—First wet it all over with distilled or clean rain water. Then mix in a measure 1 drachm of the solution of soda and 1 ounce of water, and pour this all over the plate. The probability is that it will produce no visible effect, but that will depend upon the antecedents of the plate, and the mode of its preparation. When the film has been well wetted with the soda solution, return it to the measure, add to it a few drops of the alcoholic solution of pyrogallie acid, and pour the mixture again over the film. A marvellous effect is now produced, for the dark parts of the picture immediately start out and become distinctly visible, although they do not acquire much intensity. Let this alkaline solution remain a minute or so upon the plate until it has developed all the details of the picture, then wash it off, and intensify the faint negative in the following manner:—First, pour over the film the usual pyrogallie acid developer, containing acetic acid, but no silver. This does not act as an intensi-

fier, but it neutralizes the alkali of the film, and prevents fog in the next operation. Now pour this back into the measure, add to it a few drops of a 20-grain solution of nitrate of silver, and pour it again over the film. You will now see the thin red negative which has been obtained by the action of the alkaline developer become gradually more intense, and the details of the deepest shadows appear and acquire force and printing vigour. Follow up the operation to the proper stage, then complete it by washing off the intensifying solution, and fix the negative in the usual way. Your dry plate, which, with the ordinary development, would have required ten times the exposure, has now yielded a dense printing negative, clear as crystal in the lights, red in the blacks, and loaded with details in the shadows,—in a word, equal in all respects to a good wet collodion negative which has received the same exposure under the same circumstances. This is surely a marvellous result.

"But it is not *any* dry plate prepared in *any* manner which will work with the same rapidity as a wet collodion plate. The alkaline developer will not succeed with every kind of dry plate, and we must now state the conditions of collodion, bath, and preservative, which have given us the rapid results described.

"The collodion must be bromo-iodized, and made with pure ether and alcohol, without any trace of methyl or bad ether, and scarcely a tinge of free iodine. A red collodion which liberates nitric acid in the bath, will not do; neither will a collodion simply iodized, however good for the wet process. There must be a good strong dose of bromide in the collodion, and the proportion seems to be that in which the collodion contains an equal number of atoms of iodine and bromine. The film should be tolerably creamy, but not so much from the presence of a large dose of iodide and bromide in the collodion, as from a sufficient quantity of pyroxyline. An over-iodized film is very objectionable, and ought to be avoided. The collodion should also contain the right quantity of water, for if made with absolute ether and alcohol, the solutions never flow properly upon the film; and if it contain too much water, the negative shows crapy lines and cracks when dry.

"The strength of the bath should be at least 30 grains to the ounce of water, and it should be made with pure recrystallized nitrate of silver. It may be perfectly neutral; or if acid, it should contain acetic and not nitric acid, the latter acid being a powerful retarding agent. The time of immersion in the bath should be at this season about three minutes. It should not contain any acetate of silver.

"With respect to the preservative, that with which we have succeeded best is tannin 15 grains to the ounce, and it does not seem to matter greatly whether the tannin is left to dry upon the plate, or is washed off immediately after its application. When tannin is used the edges of the film should be protected by varnish.

"Another preservative which seems to answer very well, and give highly sensitive plates, is a mixture of albumen, honey, and carbonate of soda; but we have not yet arrived at the best proportions.

"Gun arabic does not seem to answer well with the alkaline developer. It answers best with the common mode of development.

"On the whole we prefer tannin, or tannin and honey. With plates prepared in this way, and an alkaline developer, we have taken breaking waves in the fraction of a second, and portraits in two seconds out of doors, and ten seconds in the shade, the exposure being in all cases the same as for good wet collodion.

"Towards the end of July last we received from Dr. Hill Norris a packet of his rapid dry plates, for comparative trial with our own. About five weeks after the receipt of them, we exposed the first of these plates in company with a photographic friend (Mr. Matthew Whiting, of Clapham), and also one of our own tannin plates, in the same camera, at the same subject, all the conditions of light,

lens, stop, &c., being the same for both plates. We gave to both the same exposure, viz., that which a good wet collodion plate would have required under the circumstances. The negatives were developed immediately, and with the following results:—

“Dr. Norris's plate, developed in the usual way with acid pyro and silver, gave a fully exposed negative of sparkling vigorous character, clear as crystal in the lights, and dense in the blacks. It was very easily intensified and very quickly developed; and the hypo removed the iodide of silver very easily and rapidly from the film. Nothing could be better than the behaviour of this plate. The film, though not protected by varnished edges, never cracked, or blistered, or played any disagreeable tricks. Moreover, the character of the negative was exactly such as every printer likes,—that is to say, the transparent parts when laid against black velvet looked as rich as the blacks of a good glass positive, whilst the high lights and half-tones had the beautiful creamy bloom of a good collodion negative taken with a pure bath and iodized collodion. All this was highly satisfactory, and the only observable faults in the negative on closer inspection were found to be some minute round white spots having a black speck in the centre.

“The tannin plate, treated with the alkaline developer described in this article, came out equally well, and yielded as fully exposed a negative as the other, and one which would print as well, although perhaps not quite so quickly. If anything, this was the better exposed negative of the two. It is free from the white spots observable in Dr. Norris's plate; but the film required an edging of varnish, and the high lights are not so beautifully clear and transparent as in the other negative when laid against black velvet; neither is there the same beautiful surface bloom on the high lights. Both, however, are admirable negatives, and Mr. Whiting has taken them with him to show his friends, and then forwarded them to Dr. Norris. The tannin plate had been kept a week before exposure, and Dr. Norris's more than a month.

“From the two last experiments which we have made with tannin and honey instead of tannin alone, it appears that a still higher degree of sensitiveness may be thus obtained. Our present belief is, that ere long a dry process will be discovered which will go far beyond the wet in sensitiveness, unless an alkaline developer can be successfully applied in developing a wet collodion plate.”

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, October 7th, 1863.

At a recent meeting of our society M. Davanne communicated the following observations on the glass employed in photography:—

“I call the attention of the Society to a question which seems to me to possess very great interest for photographers, especially for those who, having a large business, make a large consumption of glass plates.

“In France plate glass costs so dear that we often prefer to employ blown glass, while our colleagues in England and Germany obtain glass perfectly adapted for all the purposes of photography at a very low price.

“We ought, I think, to inquire into the cause of such an anomaly. French plates are of finer quality, perhaps, although generally a little green; and they are also, I consider, stronger and better polished, but the German plates, with their delicate blue hue, seem to me quite as good, and possess the advantage of costing much less.

“These German plates are frequently finished only on one side, the other remaining rough, or nearly so. This may be an advantage for photography, for the unpolished side, by diffusing the light, may produce more softness.”

M. Davanne presented, in the name of M. Levitzky, and

on his own part also, the following observations on the employment of the sulphocyanides for fixing negatives:—

“Some months ago, a committee, of which we had the honour of being appointed a member, examined the new fixing agents proposed by M. Meynier, and recognized that, theoretically, these salts can replace hyposulphite of soda and cyanide of potassium in the fixing of negatives and positives. But practice must sanction the theory, and the difficulty of procuring these new salts, and their high price, render experiment nearly impossible. Happily, the confidence we entertained of seeing the price soon reduced, is happily confirmed, thanks to the skill of our chemical manufacturers, and the price of 60 francs the kilogramme, first proposed, soon fell to 30, then to 18, and to 9 francs, and now it is 7, and 6 francs, and even less. The sulphocyanide of ammonium is not the only one that can be employed. The sulphocyanide of potassium exhibits exactly the same properties, and each may be employed indifferently.

“We do not know if the application of the alkaline sulphocyanide to the fixing of positives has been made on a large scale; their high price has doubtless checked more than one experimenter. But this inconvenience, although much less than in fixing negatives, has permitted of its employment in a cursory manner, and one of our colleagues, M. Levitzky, has been struck with the advantages these fixing agents present over the cyanide of potassium and hyposulphite of soda.

“He states that the action of the sulphocyanide of ammonium is slower than that of cyanide of potassium in the operation of fixing, and that if we wish to make the fixing prompt, we must employ a saturated solution, or one at least of 75 to 80 per cent., but we can perform this operation in a dish, and employ a solution of less strength, which, nevertheless, must never be less than 50 per cent.

“This fixing agent gives results very superior to those obtained with cyanide. The negative is sharper, and it is remarkable that the lights retain their transparency and exhibit much more detail; while the action of the cyanide always renders the whites more or less opaque. M. Levitzky notices an inconvenience that has occurred to him; this is, in keeping the solution of the salt in the operating room, an ammoniacal odour is developed sufficient to fog collodion plates in the vicinity of the dish of sulphocyanide. This inconvenience would be avoided by using sulphocyanide of potassium.

“For our own part, we are engaged from another point of view, presenting great advantages for travelling photographers.

“For a long time we have abstained from fixing negatives on albumenized collodion obtained on our excursions, before returning to our laboratory. Cyanide of potassium presents the inconvenience of completely detaching the film from the glass plate, and in the Taupenot process we can employ only hyposulphite of soda. But carrying this salt in the box where the other apparatus is packed incurs great risk of spotting in the course of the manipulations from the jars or shocks of carriage, and we have given it up. In such cases, the alkaline sulphocyanides may be employed without risk; they leave the albumen film intact, and fix the proofs rapidly, and we think they will soon be employed by all travelling photographers, whatever process they adopt. Let us hope that the more general use of these salts will cause a still further reduction in their price.”

FORMIC ACID IN THE DEVELOPER.

SIR,—Colonel Stuart Wortley is so skilful a photographer that he could produce a good picture with materials which would be worthless in the hands of others. He knows not the danger which attends the employment of an iron developer, where large plates are used; and by less skilful photographers than himself, its stains, its difficulties of intensification, and the chances after its numerous intensifica-

tions and washings, that before the plate can be varnished its film will have split, or fallen off in rags. He, therefore, does not appreciate the value of a developer, which can be employed with a bromo-iodized collodion, instead of iron, and has treated the Sergeant rather roughly; but, I am sure, that there are many who will agree with me in thinking that our thanks are due to Sergeant Moss for his communication, and that, although he was not the first to recommend the use of pyro and formic acid, he has the merit of having been the first to give a simple formula, which may, in many cases, supersede the use of iron where a bromo-iodized collodion has been employed. I have tried his developer with three plates 10×8 . The day was dull and sunless, raining frequently, and with much wind. I used Ponting's bromo-iodized collodion in each case, and without stain or intensification I obtained a fair negative. The detail of foliage may not have been as delicate as it would have been with iron, but it was sufficiently good; so that, if there had been no confusion of the leaves from wind, I could have distinguished the ivy with which a wall is covered from the other creepers which grew on it, and I am quite sure that there is much less risk of the splitting of the film. Of the three negatives, one showed *no inclination* to split, the other two would, probably, have remained firm had I not brought them to a fire when only half dry. They were partially injured, but so slightly that had I been using iron I should have considered my afternoon's work a "bonne fortune."

I certainly gave a much longer exposure than that given by the Sergeant (perhaps owing to the dulness of the day), and my developer had rather more pyrogallie than he recommends; but this deviation from his formula may not have been an improvement.—I am, Sir, your obedient servant,

September 30th, 1863.

ANON.

MICROSCOPICAL PHOTOGRAPHY.

SIR,—In the last number of the PHOTOGRAPHIC NEWS, at page 478, there is a communication in which two claimants are named as inventors of a so-called microscopic camera; and as my name is introduced, I beg you will permit me to make a few remarks. I was certainly surprised to find that a patent should have been obtained for an arrangement, which, in its essential parts, must be familiar to all who have engaged for years past in the enlargement (by photography) of microscopic objects; and also to those who have been employed in the process of reduction. In the year 1840 I made use of a similar apparatus (to the one recently patented) for producing pictures of magnified objects on daguerreotype plates, both by daylight and artificial illumination; and in the same year I exhibited this process publicly at the Mechanics' Institution, in Liverpool. During a lecture a flea was photographed to 6 inches in length. On this occasion I used oxy-hydrogen light for illumination. By the reverse process (reduction) I produced miniature views and printed matter for examination under the microscope: these were, however, limited, as I found the mercurial deposit too coarse for any magnifying power above 20 times linear. The discovery of the collodion process by Mr. Archer enabled me to continue my experiments, both in the enlargement of microscopic objects and also in the reduction of objects to be viewed under the microscope. The deposit which forms the picture in the collodion process being very much finer than in the daguerreotype, photographs can now be taken containing more than one-hundred portraits in a surface one-hundredth of an inch square. I claim to have originated photographs for examination by the microscope, but do not imagine any merit due to me for the arrangement of the apparatus for microscopic photography; as this would naturally suggest itself to any person engaged in such experiments, and which I have used and supplied to others for so many years past.—Yours truly,

J. B. DANCER.

Manchester, 43, Cross Street, October 6th, 1863.

Photographic Notes and Queries.

DURABILITY OF GUTTA-PERCHA TRANSFERS.

SIR,—It may interest Mr. Russell, to whom we are all so much indebted, to know that the gutta-percha transfers to which I referred were made some years since, and that they are not in the least brittle. I saw them, shortly since, roughly shaken, to show their electrical condition, adhering to the palm of the hand turned to the floor, and they exhibit no brittleness whatever. I have no time, myself, yet to make experiments in this direction. I find, however, that by pouring chloroform on fine gutta-percha chips, sufficient to cover them, and, after they are soft, putting them into benzine or benzole, a good solution is obtained; and after the deposit of colouring matter takes place, I have a tolerably clear solution of gutta-percha.

C. C.

THE DISCOVERY OF ALKALINE DEVELOPMENT.

DEAR SIR,—That great unknown, "Delta," who pitches into me in a letter quoted in your last leading article—tell him, please, and your readers also, that I do not claim to be the discoverer of the alkaline development, and never dreamt of doing so; neither do I know who is the discoverer. Tell him, also, that I do not like people to say nasty things of others under a feigned name; and I consider any man who does it a sneak.

You will greatly oblige me by inserting these few lines in your next.—Yours faithfully,

THOMAS SUTTON.

Jersey, October 5, 1863.

THE EARTHQUAKE.

DEAR SIR,—Being on a tour with a friend, we were somewhat startled on the morning of the 6th inst., at 3.30 A.M. by a severe shock of an earthquake; it lasted about 5 minutes.

The air previously was very hot and close; then came a low rumbling noise in the direction of south to north, increasing in intensity, and then gradually dying away. This lasted for three minutes. To this succeeded a violent rocking and shaking motion, the bed being rocked to and fro, one of the children in an adjoining house being nearly tossed out of its crib. It may be expressed thus:—Two shocks, one much shorter than the other; after this an intense cold succeeded. I should be glad to hear if the same was experienced elsewhere, in other parts of England.—I am, Dear Sir, yours truly,

W. H. WARNER.

Madley, near Hereford, 6th October, 1863.

Talk in the Studio.

PHOTOGRAPHY FOR ILLUSTRATION.—We understand that Mr. A. W. Bennett will publish, early in the approaching season, a second volume of "Howitt's Ruined Abbeys and Castles of Great Britain and Ireland," illustrated with photographs, one of its chief features being Kenilworth Castle, and a volume of Widdoworth's poetical descriptions of the scenery of the English Lake Country, also illustrated by photographs of the scenery described, a companion volume to the "Lady of the Lake" of last year.

A PHOTOGRAPHER AND AERONAUT.—M. Nadar's monster balloon has not yet "aspired the sky," but is to do so. Your readers, I believe, know that the design of M. Nadar is to render aerial voyaging not only instructive, but pleasant; so he has constructed reading and billiard rooms, and a photographic studio, in addition to the usual living apartments. The car which contains these is two-storied, the upper floor being a terrace, surrounded by a strong railing, or *garde-fous* (*absit omen!*), from which, I presume, our travellers are to fish for birds, for M. Nadar is amply supplied with fishing tackle, which must either be intended for aerial sport, else as provision against their "falling in the sea." [Since the above appeared in the *Daily Telegraph*, M. Nadar, and about a dozen friends, made an ascent, intending to remain in mid-air for four days, but some accident to the tackle compelled an earlier return to *terra firma*.]

PHOTOGRAPHY AT THE EISTEDDOD.—A paragraph has been going the round of the press, regarding a photograph of Brinley Richards' lost umbrella, at the Eisteddod. The true particulars of it are as follows. The above-named gentleman being present at the national gathering of Welsh bards, at the

Swansea Eisteddvod, and of which institution he is an honoured and respected member, he happened to lose his umbrella twice in an audience of 7,000 individuals. Mr. W. Griffiths, an assistant to Mr. Hughes, having taken down with him a case of photographs (which is now on exhibition at Mr. Leblanc's, 57, High Holborn) for exhibition, the photographs attracted some attention, and the peculiarity of the umbrella, and the truthfulness of the photograph was such, that the umbrella was twice recovered and restored to the owner through its aid. Mr. Griffiths, writing to us on the subject, says:—"The fact being known that I am salesman to Mr. Jabez Hughes, of Oxford Street, it was inferred that Mr. Hughes was the photographer. Mr. Hughes, however, has nothing to do with the series which I am now publishing—indeed, he has not yet seen them; so that it is an error for the press to attribute them to him, although I should not be sorry for them to be connected with him, as I think they would do even his reputation credit: but it is a pity for an error to be circulated. You will see by this circular the particulars of the series to which Brinley Richards' portrait belongs. I have much pleasure in enclosing you a copy of his portrait, also one of J. C. Hughes, Esq., of Manchester, the 'Wordsworth' of Wales, and author of the original *Welsh* words of 'God Bless the Prince of Wales,' and of which the English version is a translation. To the original *Welsh* words, Mr. Richards first composed his now world-wide national air." The photographs form a very interesting series, and will be valued by all concerned in the bardic festival of the principality.

CORNWALL POLYTECHNIC SOCIETY PRIZES.—H. P. Robinson Esq., Leamington; "Stoneleigh Deer Park;" the silver medal of the first class, offered by the Society for the best photograph in the Exhibition. The Chairman of the judges of this department said "that they could not hesitate in awarding Mr. Robinson this prize." Col. Stuart Wortley, silver medal of the first class, for his studies of sea and clouds, as the best amateur collection. S. Thompson, Esq., Notting Hill, London, bronze medal of the first class. S. H. Morgan, Esq., Clifton, bronze medal of the first class, for his studies of trees, &c. J. N. Tressidder, Esq., Surgeon, H.M.I.A., £1, third best amateur collection.—A. C. STEPHENS, Manager of the Art Union of Cornwall.

ROYAL PORTRAITS.—The new King of Greece, and the Prince and Princess of Wales, honoured the fine studio of Messrs. Southwell Brothers, with a visit, a few days ago, and sat for portraits, which were very successful.

MULTIPLICATION AND ENLARGEMENT OF NEGATIVES.—Whilst in Newcastle, we visited the studio of Messrs. Downey, Brothers, where we saw some examples of remarkably successful reduplication and enlargement of negatives. The demand for their interesting series of card and other portraits of statesmen and other public men, obtained in London this summer, being very large, they have felt it desirable to facilitate printing by multiplying negatives. This they effect in the usual manner by producing first a transparency and then another negative, and in many instances this is effected with such skill that it is difficult to distinguish the copies from the originals. An enlargement of the head of Lord Palmerston is one of the most successful examples by this method which we have ever seen, and is round, delicate, soft, and well-defined. There is no speciality in the mode of working beyond the exercise of care and judgment.

To Correspondents.

PERCENTATOR.—The ready decomposition produced by the reaction of the iron developer and the free nitrate solution, on a plate, may be due to various causes. A neutral bath and too little acid in the developer may cause it; the presence of organic matter in the nitrate bath will frequently cause it; both or either of these conditions are likely to cause it in hot weather. 2. A "concentrated solution" is not a very definite term, but, when used, is generally meant to describe a solution stronger than is usually employed. For instance, in chloride of gold, a solution containing one grain to an ounce would be called concentrated; whilst, in nitrate of silver, a solution containing one hundred grains to an ounce of water would be regarded as concentrated. 3. Sulphide of silver, which is the precipitate produced by adding liver of sulphur to solutions containing silver, must be reduced in the crucible, it cannot be properly converted into nitrate of silver, without first being reduced as metallic silver. 4. If the bath for exciting negatives be too weak, the image will be feeble, and formed only on the surface instead of in the film.

N.—In our own experience, nearly equal rapidity may be gained by the use of pyrogallic and formic acid, and by the ordinary iron developer; but we prefer the negative produced by the latter, as more delicate and perfectly

detailed, giving a more perfect register of every gradation in the subject. 2. Careful drying is of the utmost importance when a film is disposed to crack; but, unless it be so disposed, the precautions you describe are not necessary. The fact, that the varied remedies to which you refer are recommended, may either imply that various causes will produce the same result, or that much uncertainty or ignorance prevails as to the real cause. We know that, with some collodions, the tendency exists, and that others are quite free from it; and, whilst the consistency of the collodion, and the proportion of solvents, may in some degree modify the tendency, its primary cause is, we believe, in the character of the gun-cotton. Nevertheless, whenever the tendency exists, careful drying is one efficient mode of preventing mischief. 3. We do not regard the strongly expressed opinion to which you refer as of much weight, and we fear it is sincerely impartially given. The mass of evidence which reaches us from the best authorities, is in the opposite direction, very decidedly, those of the maker not recommended possess all the good qualities of the other with greater depth of definition besides. 4. The letter was in type. Thank you for your attention in the matter of the back numbers.

W. W. WILSON.—The only large views of Swiss scenery, which we know, are those of Bisson, Freres; we do not know whether they have any agents in this country.

A. H. WARDLOW.—We will propose you, and you can attend the future meetings.

SUBSCRIBER G.—We prefer those of the London maker, decidedly.

T. P.—Lime water is common water saturated with hydrate of lime. The colder the water, the greater the proportion of lime it will dissolve. If exposed to the atmosphere, it quickly becomes covered with a pellicle or film of carbonate of lime, from the action of carbonic acid in the atmosphere. It is strongly alkaline. 2. Common soda is the term used for the carbonate of soda used by the laundress. 3. The addition of chloride of iron to sulphate of iron would only be injurious in the developer, as the chloride would precipitate the free nitrate of silver on the plate as a chloride. 4. Waved marks in the background may proceed from many causes, but very frequently arises from the use of a thick cadmium collodion. 5. Hyposulphite of soda may be kept in solution without injury, if it have not been used. 6. We do not quite understand your question, "What chemical suffers most suddenly visible alteration in diffused light?" Chloride of silver darkens most rapidly. 7. Cyanide of potassium is a very energetic solvent of the salts of silver, but it is not suitable as a fixing solvent for chloride of silver in positive prints.

JONAH.—1. Yes. 2. Probably. 3. We have not tried it; but probably, yes. 4. We do not know any better at the price.

FRANCIS VINCENT.—A strong bath, unless freely acid, is much more prone to give streaks than a weak one. You may probably get rid of the streaks by adding nitric acid freely, which with fully bromized collodion may be done without loss of sensitiveness; or by neutralizing the bath with carbonate of soda and sunning the solution for a day or two.

OLD SUBSCRIBER.—You may neutralize and sun a printing-bath if you choose; but we should not think it necessary. 2. It is not essential to have a printing-bath acid at all if it be strong enough; but if it be at all weak it is better to have a slight trace of nitric acid present to prevent the albumen being dissolved. A new bath of 60 grains of nitrate of silver to an ounce of water will generally give good results without any addition.

HENRY.—We see no especial advantage to be gained by dispensing with a sliding body; but if you wish it, the plan you propose of having several grooves to admit slides at distances from the lens varying from 33 inches to 15 inches may be used. The chief difficulty to be guarded against in such case is the risk of admitting light through some of the many openings. 2. We have not made comparative trials of the two collodions you name, but have found both good. The one by which your print was taken we have fancied the cleanest, the other the most sensitive. The print appears to be very good.

L. M. II G.—It is difficult to state with certainty the cause of the spots without knowing more about the circumstances. They very much resemble the result produced by placing any unvarnished negative, which has been intensified with mercury, in contact with the sensitive paper.

A POOR AMATEUR.—It does not necessarily follow that a manufacturer who guarantees his goods "inferior to none," whilst they really are inferior, is a cheat. He may fancy them inferior to none, and his judgment may be at fault. A man's opinion of his own productions is rarely quite impartial. In the case you quote, as in most cases, it is probable that the lowest price is worst. We should not, for ourselves, select either; but we cannot in this column undertake the invidious task of recommending any by name.

J. N.—Use good water colours without any addition, but clean water. If the colours work greasily add a little prepared ox gall. Newmans make a "preparation" which may be used with advantage prior to applying water colours to albumenized paper. A little gum water may be applied to the shadows. Wall's work on colouring, or Newman's "Harmolous Colouring," applied to photographs, will be useful to you.

IAON AND AMMONIA.—The double salt of iron and ammonia may be used very similarly to ordinary protosulphate of iron. A solution containing 50 grains of the double salt, and 29 minims of glacial acetic acid to the ounce of water, gives excellent results.

ART IN PHOTOGRAPHY.

THE questions "What is art?" "What are the qualities called 'artistic'?" "What is 'artistic feeling'?" have often been asked, and very much has been said and written for the purpose of defining and limiting art and art qualities. Very often what has been said and written has simply "darkened counsel by the multitude of words without wisdom." It is difficult to deal with the subject in a mere definition, as the appreciation of art is as much a matter of feeling as of knowledge. As an aid to comprehending the subject, we cannot forbear calling attention to, and repeating, a passage in Colonel Stuart Wortley's admirable paper on "Photography in Connection with Art," which, by the courtesy of the writer and of the secretary to the Cornwall Polytechnic Society, we are enabled to give on another page. The Colonel observes:—

By a feeling for art, I mean that intense appreciation of the beauties of Nature that leads us not to be satisfied till we have, in our humble way, done our best by means of such arts and such contrivances in our power, whether drawing, painting, or photography, to reproduce faithfully what we most love and enjoy in Nature; and I maintain that the highest art, the purest taste, is shown in the most scrupulously faithful transcript from Nature itself, because nothing, and no imaginary form or colouring, can equal, or, I might indeed say, approach in beauty what, if we care to look for it, and know how to find it, can find for ourselves in Nature. And it is pre-eminently this earnest desire to seek for and discover the beauties of Nature, and the knowledge of how and where to find them, that distinguishes the artist from the mere painter or photographer.

This love for, and earnest appreciation of, what is beautiful in Nature, from the primeval forest in its solemn grandeur, to the tiniest leaflet or blade of grass that grows by the way-side; from the wild and untameable glories of the eternally changeful sea, to the simplest ripple of the little brooklet just leaping into life out of the mountain side: from the manifestation of the loftiest, the most stirring emotions which ever aroused nations or startled humanity, to the expression of the simplest feelings which illustrate the "short and simple annals of the poor"—this is artistic feeling. The rendering of this feeling, the embodiment with an adequate expression of the beauties of Nature, by whatever means or materials, is Art. Artistic feeling is generally a natural endowment, but it may be largely increased, if not entirely originated, by cultivation. But to give artistic feeling expression requires knowledge, and hence becomes important a study of the experiences of those who have left glorious legacies of beauty to mankind, and observation of the rules—which are not arbitrary—growing out of those experiences: rules which should guide, but not trammel. If these definitions of artistic feeling and of art be correct, on what possible plea can photography be denied the power to give them embodiment?

MR. ROBINSON'S NEW PICTURE.*

MR. ROBINSON has for some years past set himself a task, which he performs with religious care. Whilst attending, as every man must, to the every-day routine of his profession of portraiture, making pictures of his sitters where he can, and letting likenesses serve where pictorial results are impossible, he also resolved to produce, at least once every year, something for photography, something to show the capabilities, and, if possible, elevate the position, of the art he loves, and by which he lives. Whilst giving the "pot-boilers" every legitimate attention, each summer must yield something for the honour of the art and the artist. The production of large pictorial compositions, by printing from several negatives, is the speciality to which Mr. Robinson has devoted his higher attention, believing that if brain and fingers are sufficiently capable, photography presents appliances and facilities for producing pictures capable of satisfying all the requirements of true art, and of gratifying the art-tastes of all who are content with delications of Nature as she is, and do not crave for what Ruskin calls the "audacious liberty of that faculty of degrading God's works which man calls his 'imagination.'"

In Col. Stuart Wortley's admirable paper on Photography in Connection with Art, given on another page, he remarks that "composition photography, more than any other, shows how difficult it is to obtain really artistic results in photographs; and he further adds his conviction that these difficulties "will always prevent that class of photography from rising beyond a certain level." We can endorse these remarks; but it must be with a qualification. The first part of the sentence states a general truth, applicable to almost any subject. The higher branches of any art most strikingly show its difficulties; the nobler the results sought after, the more apparent will be the inadequacy of the means to attain them. But these difficulties overcome by ability and perseverance; this poverty of material and appliances surmounted by skill and rightly applied knowledge, the results are immeasurably superior to those produced by less skill and simpler agencies. That these difficulties will prevent composition photography from rising beyond a certain level, is, if taken literally, a simple truism; but if it imply that the level is a low or insignificant one, we think that the progress which has been already made in Mr. Robinson's hands alone, points to a very proud future for this branch of the art; and we are sanguine enough to believe that when the same amount of careful art-study and varied ability, which have been given to the older arts of painting, &c., shall be applied to photography, it will be found that neither are the materials intractable nor the results unworthy of the effort.

Without the facility of combination which has been designated "composition photography," the scope of our art must be greatly limited, either to the production of small pictures,

* AUTENS: Photographed from nature in several negatives, by H. P. Robinson, Leamington.

or, more often, to mere portions of pictures. Col. Stuart Wortley has well denounced the mere "photographing of foregrounds," and insisted on the importance of a sky to complete a landscape. The composition photographer goes farther; he insists on all the parts of a landscape, and on the presence of figures, not merely to aid the composition, but to give the picture human interest.

"All true landscape," Ruskin observes, "whether simple or exalted, depends primarily for its interest on connection with humanity," and the elements of this interest Mr. Robinson can best secure, he thinks, by the means he adopts. His latest work is entitled "Autumn," and it may be very properly designated a landscape with figures, in contradistinction to several of his former pictures, which have consisted of figures with landscape background. The titles indicate the difference in intention. Take two of the most important of former years; we have "A Holiday in the Woods," in which the children playing in the thickly wooded neighbourhood of Kenilworth, form the feature of interest. In "Bringing Home the May," the illustration of the rural pastime is the primary motive of the picture, the landscape is only accessory. But in the picture before us, the landscape claims an important part in the intention of the composition, and not less than the autumnal suggestion of the figures, with their sheaves of gleaned wheat, indicate the subject of the picture. The lines from Scott, which accompany the picture, with Mr. Robinson's happy facility of quotation, admirably describes the scene.

"—The distant reapers' mirth we hear,
The last blithe shout hath died upon our ear,
And harvest home hath hushed the clanging wain:
On the waste hill no forms of life appear,
Save where, sad laggards of the autumnal train,
Some youthful wanderers glean few ears of scattered grain."

The first glance at the picture charms us. We see a bold and well-composed foreground, with groups of rustic figures resting by an old stile, or reclining on a bank of brake and heather, which overhangs a river. Beyond, a landscape such as, in photography, rarely glads the eyes of man. Stately trees, which spread their long evening shadows far over the landscape, form a grove winding gracefully by the side of a sparkling rivulet, whose fantastic curves carry the eye into the dim distance. Over receding grove, and brook, and plain is spread a fairy robe of atmosphere; and it is atmosphere, with the mellow light of an autumn evening; not the misty, foggy, appearance which quickly closes up the view and then passes for an atmospheric effect. The eye here reaches for miles, and forms, whilst they diminish and grow dim, are still slightly made out, as seen through the translucent veil of atmosphere. The tone and feeling of the picture, and the sheaves of wheat at the feet of the gleaners, at once tell us it is autumn; but so wonderfully full of tone and gradation is the picture, so suggestive is its rendering of colour, that no stretch of fancy is required to clothe it with all the gorgeous hues, the varieties of golden brown and yellow, of green, of russet, and of crimson foreground, of blue and purple distance, which belong to declining summer, or harvest time. Such is the first impression; but let us describe it in sober detail.

The size of the picture is twenty-four inches by fifteen inches. In the foreground stands the principal group, two female figures, resting and watching with interest something or somebody approaching. The hand of one is raised to shade her eyes from the glinting sunlight, which just tips her face. A large sheaf of newly gathered wheat at the feet of one, and a smaller one under the arm of the other, bespeak their late employment. They lean against a grand gnarled and half decayed old tree trunk, which forms part of a stile, on the step of which rests a younger bonny little country lass, who grasps her gleaned sheaf on her lap, but turns her head to look in the same direction as the elder girls. To the left, sitting with his legs across the upper bar of the stile, is a lad, evidently a lazy dog: he leans back against another tree trunk which forms part of the stile, with an air of the supreme indifference, the very picture of *insouciance*,

or, as a somewhat slangy friend has just phrased it, "devil-may-careishness." His presence during the day has not, we feel sure, added to the size of the sheaves gleaned; hazel nuts, black-berries, crab apples, and similar reflections from the hedge-rows, have had more charms for him than following the reaper or wandering amongst the stooks to glean the scattered ears. Detached from the principal group to the right of the foreground, which is varied with tangled clumps of brackens and bramble, is another figure, with her gleanings, seated on the ground, looking over the landscape, her back only being seen. Stretching over the whole of the picture is a most charming landscape, well wooded, but still open. Commencing on the right of the picture, a little behind the foreground, just in advance of the middle distance, is a noble grove of trees, receding far away, and reaching the extreme distance, within a few inches of the other end of the picture. Meandering at the foot of the grove, with devious wayward course, is a lovely brook, or river, with exquisite sparkling lights among the deep shadows of the reflected trees. To the right of the picture, from the foreground to the extreme distance, is an immense stretch of level park land, just sufficiently broken with one fine tree in the middle distance.

The feeling of this, as of almost all Mr. Robinson's compositions, is essentially idyllic; but here, more than in any other, is the sense of rural quiet, and of the vast grand repose of Nature. A few minutes' quiet contemplation of the picture has a soothing, tranquillizing effect on the mind; we seem to mingle with the scene, and enter into its autumnal feeling of fullness, ripeness, rest. The time is evening, as we have already said. A gleam of parting sunshine lights up part of the group, and of the trees, and rivulet, whilst the rest is in diffused light or shadow.

But the wonderful charm of the picture, and its leading characteristic, is the perfect sensation of atmosphere. This essential quality of English landscape is here more perfectly illustrated than we have ever seen it effected by photography. The foreground and figures are very vigorous, beautifully rounded, and soft, but still brilliant and forcible. The huge trunks which bound the stile stand out bold and massive against the fine oak in the middle distance; and this is forcible, compared with the trees beyond, which recede with exquisite gradations into the most delicate and tender distance, which is again surmounted by light, delicate stratus clouds. The little rivulet, which, as it gracefully winds along, also takes the eye gradually into the distance, shows the atmospheric effect on its sparkling lights and mysterious-looking shadows. There is a lightness, a delicacy, an airiness about the whole picture, which is as novel and surprising as it is beautiful. Every one is familiar with a fact common to photographs, especially large ones, however perfect; the first glance at them, when hung on a wall at a little distance, gives a certain impression of heaviness. There is a want of light and transparency, which at first suggests that the picture is too dark, even though it be a light impression. In this picture there is an entire absence of that effect—the first glance satisfies us with the general effect, and a continued examination delights us with its truth and beauty.

As an artistic composition, this picture is very admirable, and is arranged with sufficient subtlety to conceal the art. The masses and lines are perfectly in keeping with rule, without any formality: the pyramidal form may be easily traced, but it is formed by the natural relation of the objects, so that it appears to be the result of accident, rather than design. The perpendicular trunk, which forms part of the stile, bounds the picture on the left, supporting the whole and giving solidity. The ferny bank in the right foreground, which conceals the nearest part of the brook, and the back of the reclining figure, stand out in bold and wonderful relief against the stretch of open ground and distance. The lovely little stream, apart from its own peculiar beauty, does its office so well that it reminds us of the little white dog in one of Gainsborough's pictures, in

reference to which, when asked by an old lady why it was there, the artist replied, "To carry the light through the picture." The expressions and attitudes of the figures are perfect, and in admirable keeping with its purpose. An art connoisseur, who examined the picture in our study a few days ago, exclaimed, "This is surely not a photograph; it is a painter's composition." The picture is, nevertheless, for the most part, a transcript of Nature exactly as it stands; and we have gazed with delight on the scene in Stoneleigh Park, which forms the important part of the landscape, so that to us it possesses the added charm of *vraisemblance*.

Photographically speaking, this is, moreover, the most perfect composition picture we have seen. The gradations are more perfect and delicate, without the least sacrifice of roundness and vigour, and it is to its excellent photographic qualities, as well as the skilled composition, that much of the atmospheric effect is due. We may here remark that in this respect the picture is a triumph of a process we have so long and steadily advocated—we mean the use of bromo-iodized collodion and iron development. This is the first composition picture Mr. Robinson has produced with these agents, a simply iodized collodion and pyrogallie acid development having been used before for all his large pictures. In this he has used Mr. Blanchard's bromo-iodized collodion; and the picture is the best yet produced, especially exemplifying all the qualities claimed for the process. It is from four negatives, and is more easily combined in printing than any former similar picture: and Mr. Robinson remarks, that whilst it more perfectly realizes the conception he had in his mind to begin with, it is produced by a less expenditure of photographic means than any former similar composition.

Mr. Robinson has also just produced two or three other charming large pictures. One is a clever *genre* study, entitled "Somebody Coming," consisting of two rustic figures at a stile, one of whom cries "somebody coming" as she archly glances at the approaching sweetheart of the other, who averts her head. The others are two very fine views of Warwick Castle. One, an often repeated subject, the view from the bridge, with the Castle embowered in foliage reflected in the river, an admirable illustration of the lines from Milton's *L'Allegro*, which accompany it:—

"Shallow brooks, and rivers wide,
Towers and battlements it sees,
Bosomed high in tufted trees."

It is, notwithstanding the repetition, the finest picture of the subject which has yet been produced. These will, doubtless, together with the large picture, be hung at the exhibitions of the forthcoming season.

PHOTOGRAPHIC CHEMICALS:

THEIR MANUFACTURE, ADULTERATION, AND ANALYSIS.

Zinc (*continued*).—The oxide of zinc previously mentioned as obtained by the ignition of the metal, is, of course, anhydrous. A hydrated oxide, which will be found very useful in the laboratory for many purposes, on account of the ease with which it dissolves in, and neutralises, small quantities of acids in solution, as well as for other purposes, may be prepared by adding to a moderately dilute aqueous solution of nitrate of zinc a solution of potash,—adding the latter gradually, and stopping before the whole of the oxide is precipitated. A light, flocculent precipitate will come down, which must be washed with hot water until no zinc is detected in the liquid which runs away. If an excess of potash is added to the solution of zinc, the precipitate will always contain potash, which no amount of washing will remove. The precipitate must be allowed to dry in the air, and preserved in stoppered bottles, to prevent its being contaminated with the acid vapours always present in the atmosphere.

In speaking of the advantages arising from the use of zinc white in painting, we mentioned that one great benefit

consisted in the white colour of the sulphide. The anhydrous sulphide of zinc is not perfectly white, but has a yellow tinge, which is absent in the hydrated sulphide: the latter is produced by passing a current of sulphuretted hydrogen gas through a solution of zinc, either alkaline or containing only a very weak free acid, such as acetic acid. If mineral acids are present, such as hydrochloric or sulphuric acids, the sulphide will be imperfectly, or not at all, precipitated. This precipitated sulphide contains one atom of water: it readily dissolves in acids.

A hyposulphite of zinc is known, but it is very easily decomposed. If zinc is dissolved in an aqueous solution of sulphurous acid, and the liquid is then gently evaporated, sulphite of zinc crystallizes out at first, and hyposulphite of zinc remains in solution. The hyposulphite cannot be obtained in a solid form. Upon evaporating its solution at the ordinary temperature, either in air or in vacuo, a precipitate of sulphide of zinc is formed, and trithionate of zinc remains in solution. This again splits up upon further evaporation, so that, ultimately, there remains a mixture of sulphur, sulphate of zinc, and sulphide of zinc, sulphurous acid having been evolved.

The principal salt of zinc met with in commerce is the sulphate. This is produced in large quantities by roasting ores containing sulphide of zinc; the two elements of this compound absorb oxygen from the atmosphere, the zinc becoming oxide, and the sulphur sulphuric acid, which, combining, form sulphate of zinc. The whole is then treated with water, and the solution evaporated to the crystallizing point. The salt thus obtained is known in commerce as zinc vitriol; it is very impure, but may be purified by recrystallization. This salt is likewise obtained in considerable quantities, when a galvanic battery is in frequent use. The force being generated by the solution of metallic zinc in sulphuric acid, the result of a few hours experimenting with the electric light produces more sulphate of zinc than the operator usually knows what to do with. We have for the last few years been working somewhat extensively on the electric light, and have at various times taken the trouble to collect and preserve the crystallized sulphate of zinc, but the commercial value of this salt is so trifling that we have now come to the conclusion that it is cheaper to throw it at once down the sink than to devote any time to its crystallization or purification. In a chemical laboratory, where large quantities of oxygen gas are frequently required, it might be worth while to preserve the sulphate of zinc with the object of preparing this gas from it. When heated to a bright red heat, sulphurous and sulphuric acids are given off together with oxygen gas; this can be thoroughly purified from the accompanying acids by being passed over slaked lime.

When iodine and zinc are brought together, they combine with slight evolution of heat, forming a colourless iodide of zinc which dissolves upon addition of water, and when evaporated down to the crystallizing point, separates in the form of anhydrous octahedrons. Iodide of zinc, when heated in the air, fuses and partially sublimes in the form of beautiful four-sided needles; the greater portion, however, absorbs oxygen, and gives off iodine vapour, being converted into oxide of zinc, and a similar decomposition takes place when iodide of zinc is freely exposed to the air at ordinary temperatures; it is very deliquescent, and owing to the ready separation of iodine from it, is not a very good salt for photographic purposes.

Bromide of zinc is far better adapted for the use of the photographer than is the one just described. Zinc and bromine do not combine when merely placed in contact, like zinc and iodine, but by passing bromine vapour over red hot zinc, the two combine, forming a colourless liquid, which solidifies on cooling to a crystalline mass. The easiest way to form bromide of zinc, is to dissolve the metal in aqueous hydrobromic acid, hydrogen being evolved. Upon evaporating the solution to dryness, and heating, the residue sublimes in white needles, which are the anhydrous bromide. They

deliquesce rapidly in the air. Unlike the iodide of zinc, the crystallized bromide is not anhydrous, but contains one atom of water: when its aqueous solution is evaporated until a pellicle forms on the surface, and then set aside to cool, it solidifies to a mass of small indistinct crystals. These must be rapidly dried between warm blotting paper, and then transferred to a warm stoppered bottle. Bromide of zinc is soluble both in alcohol and ether.

Chloride of zinc is very readily formed, and is a salt of some considerable value for many purposes. It may be prepared either by the direct action of chlorine gas upon zinc, in which case it is produced in the anhydrous condition, or by dissolving metallic zinc in hydrochloric acid. The solution is rapidly effected with evolution of hydrogen, and when evaporated to dryness, and heated to dull redness, the anhydrous chloride is left behind. When cold, it has the appearance of a whitish grey, waxy, semi-transparent substance, which is excessively deliquescent, and must therefore be kept in tightly stoppered bottles, the stoppers of which should be smeared with paraffin. Fused chloride of zinc is of great use in the laboratory, for drying liquids and gases. Owing to its powerful affinity for water, it instantly seizes upon every trace of this body, and is largely used in cases where the action of chloride of calcium is not sufficiently energetic.

ON PHOTOGRAPHY IN CONNECTION WITH ART.

BY THE HON. LIEUT.-COL. STUART WORTLEY.*

IN the paper I am about to read to you, I shall avoid, as much as possible, wearying you with any of the technicalities of the various processes of photography, being more anxious to draw your attention to the position which photography does hold, and is capable of holding, in connection with the fine arts.

To begin, by alluding to photographic portraiture, as carried on in the present day.

I must first ask you to disabuse your minds of a common error into which most people fall, namely, that a photograph because it is taken as it were by machinery, must necessarily be a likeness.

This is not the case, and, for the following reasons. The photographic portrait lens is not a perfect instrument, and of necessity magnifies the objects that are nearest to it, and makes them out of proportion with those situated in a plane somewhat further from the instrument. To prove this, you have only to look over any collection of photographic portraits, and you will at once see that the hands, or feet, or any object prominently brought forward, are larger than they should be, to be in due proportion. This defect, of course more visible in the case of a hand, foot or other large object, alters the *proportion*, and, indeed, the *expression*, of a sitter's head and face.

If, then, in posing a sitter, you allow the chin to be elevated, or brought forward, it is of course appreciably magnified; and the forehead and eyes being thrown back at the same time, are diminished, and a coarse, foolish expression given to a face that may be full of intelligence and refinement of feature.

This defect is of course much greater in a cheap, bad lens, than in one by any of the best makers; though it is, as I hope you will have understood from the remarks I have made, one that can easily be guarded against.

But now we enter on a wider field, and we get to the true difficulty in photographic portraiture; it is, that without knowledge and taste, it is impossible to give a pleasing and natural pose to a sitter.

Look again at a collection of photographs; you have probably the pictures of many, and doubtless very pretty young ladies in your respective albums. Now, honestly, how many of those photographs do the young ladies justice?

Do any? Are not the majority atrocious libels? In how many of the positions selected by the photographer would a portrait painter have placed his sitter? It appears singular that such an utter want of artistic feeling and taste should be shown in the majority of photographic portraits, but such is undeniably the case. It is not the want of colour in a photograph that makes it so unsatisfactory. You must all of you have come across, occasionally, most charming portraits in monochrome, chalk and crayon drawings, in sepia, and even with pencil and pen and ink, and occasionally a photograph. Shall we try and inquire why the good photograph is the exception and not the rule?

In many cases, the professional photographer has taken up photography as a profession, and so long as he makes it pay he is content. He does it by machinery; he has no knowledge of art, no feeling for the beautiful; and in many cases, as any one can see, is entirely ignorant of the optical properties of his lenses. And the amateur, he takes to photography because it is so nice to be able to get pictures of all one's friends! He gets *photographs* of them certainly, but between photographs and pictures there is a wide chasm, bridged by a narrow plank, across which not many of our amateur portraitists have yet walked, and as few of our professionals.

Honour, therefore, to those who have done so. In the Photographic Society's Exhibition this year some exquisite pictures were shown by some of our leading photographic portraitists. Pictures thoroughly deserving of anxious and careful study by any one desirous of excelling, whether amateur or professional. I cannot, however, call to mind any good portraits by amateurs, with the exception of four medium sized ones by Dr. Diamond.

Perhaps our best amateurs do not like exhibiting the pictures of their relations and friends for criticism. I can sympathise with that feeling; but anyhow the result was that, with the exception above mentioned, amateur portraiture fell very, very far below the results of the professional gentlemen exhibiting.

If I may give a word of advice to amateurs anxious to take up portrait photography, it would be to recommend them strongly to adopt the style of taking the head and shoulders only, making the head about the size of a shilling, and carefully vignetting it, using always a plain background, varying the colour of the latter according to the colour of the sitter's hair, dress, &c., &c.

I now propose to draw your attention to landscape photography, a branch of the art more practised, I think, by amateurs, but requiring on their part more knowledge of high art, more feeling for all that is beautiful and glorious in nature, and more perseverance and hard work before they can attain to eminence. And yet, what a charming study it is; how much better you feel, how much more contented and happy, sitting wrapt in contemplation of the beauties of nature, you forget insensibly the worries and trivialities of ordinary life; you are unconsciously led to think of higher things, to think perhaps of things that never struck you so forcibly before; gentle, peaceful thoughts find their way to the surface out of long unused and long silent depths of the heart; your best, your tenderest feelings all rise under the influence of nature in its witching beauty; and when the time comes that you must return, when the last rays of the setting sun have gathered the last gleams of gold and purple from the delicate clouds floating on the horizon, and left them to put on their sad coloured grey tints, so quickly to turn to black as if mourning his departure, you rise with a sigh, and turn wearily back to commence anew the constant strife and struggle with the many vexations of life, conscious, however, that you have higher hopes, and aspirations; and feeling, if, to use a familiar saying, "your heart is in the right place," an awakening of long dormant emotions, and a quickening, so to speak, of the good seed that lies in the depths of every heart, choked, too often though it be, with poisonous weeds, and having, perhaps, so far quickened it that from that time forth it shall silently

* Read before the Royal Cornwall Polytechnic Society.

and imperceptibly pass from seedling to bud, and from bud to blossom, finally to produce that good fruit fit to be gathered by, as we must all earnestly hope, Him who laid the good seed in our hearts, the great Author of all that is beautiful and wonderful in Nature, the All-Powerful.

Yet, it is not only a charming, but it is, to those who have a feeling and a love for art, an entrancing study; and by a feeling for art I mean that intense appreciation of the beauties of nature that leads us not to be satisfied till we have, in our humble way, done our best by means of such arts and such contrivances in our power, whether drawing, painting, or photography, to reproduce faithfully what we most love and enjoy in nature; and I maintain that the highest art, the purest taste, is shown in the most scrupulously faithful transcript from nature itself; because nothing, and no imaginary form or colouring can equal, or, I might indeed say, approach, in beauty what we, if we care to look for it, and know how to find it, can find for ourselves in nature. And it is pre-eminently this earnest desire to seek for and discover the beauties of nature, and the knowledge of how and where to find them, that distinguishes the artist from the mere painter or photographer. No one shows this more strongly than our great landscape painter, Turner. His glorious sunsets, his magnificent effects of light and brilliancy, the exquisite beauty of his landscapes, are only the truthful results of his careful and conscientious study of nature, and his constant communing, so to speak, with nature; and that study alone made him the great and wonderful painter that he was.

It is hardly possible to over-estimate the influence exercised by the study of nature and art on the masses. In a most able lecture, by Lord Stanley, on "Art Education," he takes occasion to mention his conviction that the power of appreciating the beauties of nature and art is greater in our own countrymen than in the inhabitants of any foreign land. I have long had the same opinion myself, founded on my personal experience abroad; and it is this that leads me so earnestly to urge upon my present hearers the study of nature, confident that they will open for themselves a new fund of enjoyment and interest, of the delights of which they have previously had but little conception.

I am afraid you will think I have needlessly inflicted this long digression upon you, but it is not so. In this lies the germ of what I am anxious to bring before you, that if you aim at art in photography you must study nature, and you must give as faithful a transcript of nature as you can. You are all of you familiar with the style of photography that I can only call the photographing of the foregrounds, the glorious beauties of the sky being represented by a piece of white paper. How singular it is that anyone can be contented with such productions when more study and more care would enable him to produce pictures and not only photographs. No one of late years has done so much for art photography as Mr. Wilson, some of whose charming representations of water and sky you have doubtless seen. I am quite sure that in no view where it is possible would he now be contented to take a photograph without giving as faithful a representation of the sky as of the landscape.

Suppose a painter were to say, "Well I cannot be at the trouble to do skies or clouds to my landscapes, people must be content with carefully painted foregrounds," what should we think of that individual? who would look at his pictures? what would the photographer himself say to them? Then, what does he imagine artists and all who have a feeling for, and a love of, nature, think of his photographs? I hold all such productions to be unfaithful to nature, and untrue to art.

Then, if any of my hearers have any idea of taking up photography as an art, I hope they will commence with a determination not to be content till they produce photographs as faithful to nature as possible, and thus rendering them worthy to be classed as artistic productions.

They need not despair of being able to do this; one of the best pictures in the Photographic Society's Exhibition

was by an amateur, Sir A. MacDonald; a piece of rock scenery and sky—a truthful and beautiful study. Many professional gentlemen have taken charming scenes. Messrs. England, Blanchard, Rouch, and others, have all made their processes public. There is no difficulty that is insurmountable; why then do the vast majority remain on the lowest round of the ladder, contentedly watching others climbing nearer and nearer to the summit.

But in addition to the real feeling for the beautiful, some *knowledge* is desirable, some study of the works of celebrated painters, in order to know how to combine the various beauties of nature.

To give an illustration of my meaning:—A view may be very beautiful from a certain point, but it might happen that by moving two or three yards one way or the other, you may make exactly the same view more available, as a picture, by including some object for the foreground, such as a mass of rock, an old gate, the trunk of a tree, or any object that may happen to be within reach.

Attention to this is conspicuous in the works of a talented photographer, whose name you doubtless know, Mr. Bedford.

There are many other branches of photography to which I might call your attention; the copying of pictures, photolithography and its various processes, and composition photography. But I am, in this paper, anxious to confine myself to photography in connection with its claims to be considered as a fine art.

Composition photography, more than any other, shows how difficult it is to attain really artistic results in photography, and shows most forcibly the weak points of photography in its claims to the rank of a fine art. Wonderful results may be achieved considering the means at our disposal, but the insurmountable difficulty of controlling the sitter's expression of face, not to mention other minor difficulties, will always prevent that class of photography from rising beyond a certain level, and will always remind us that photography has much that is mechanical, and that it is necessary to obtain far greater rapidity than any process at present possesses, before composition photography can worthily assist in claiming for photography in general the dignity of a fine art.

In conclusion, I should strongly recommend an amateur to adopt a rapid process, so as never to have any difficulty in getting life into his pictures. A man in the foreground, a cow, a waggon and team, give life and reality to a photograph, and are often of the utmost value, and even necessity, to the composition of the picture.

In the present state of photography, with the minutiae of the processes carefully laid down by experienced photographers, two or three months' hard study should make any lover of nature and art an accomplished photographer; and, if he knows somewhat of chemistry, or studies it a little at the same time, so much the better.

I find myself offering a great deal of advice, much more, probably, than any one will ever take, but I must add a little more still. In taking up a process, see that you take up one practised by somebody whose productions bear out what he says; it is no use being told by Mr. A, or Mr. B, in a photographic journal, that by the use of such and such a formula he obtains better pictures than any one else. Where are they? Perhaps he sends the Editor of the paper one good specimen, keeping his ninety-nine bad ones at home. Books and pamphlets on photography are plentiful, letters written to the journals are legion, and yet, I doubt if one in every twenty authors has ever shown a really good picture. And, when you take away the standard works on photography, by Messrs. Hardwich, Sutton, Hunt, Lake Price, and one or two others, the three first being accomplished chemists, as well as photographers, few, indeed, are left of which the authors are known as accomplished photographers.

Many articles are written solely with trading motives; they declare a certain process can only be worked with Mr. C's collodion, or Mr. D's acid, or printed on Mr. E's paper, and are very, very full of humbug.

Many of the most eminent photographic chemists are hardly ever mentioned, except occasionally some one draws attention to any new or very superior article made by them. They have no need of such shallow puffing, and never resort to it.

In giving you some guide to a process that you would be wise to adopt, I have already made mention of three or four of our most eminent men, the minutiae of whose method of operating have been fully published. Many others have written most valuably on the subject, Major Russell, Mr. Vernon Heath, Mr. Wharton Simpson, and many whose names I do not at this moment recollect; and any photographer in difficulties will always obtain advice and assistance from the Editors of either of the photographic journals, of which we have four, all the gentlemen in question being thoroughly at home in chemical, as well as artistic knowledge of photography. I may mention here that my own pictures were obtained by a process devised by myself two years ago, the main points being a large amount of bromide in the collodion, liberal use of nitric acid in the bath, which must be made of the purest silver, and formic acid in the developer. *Carefully* using these in their proper proportions, which constant experiments enabled me to obtain, I consider that I can obtain my pictures with as great rapidity as the quality of the light will allow; and where the light is good and clear, I am unable to open and close the lens with sufficient rapidity.

If I have in any way given one of my hearers a bias towards attempting artistic photography, I shall be very glad. I am confident that by photography pictures are to be obtained far superior to anything else ever produced in monochrome, and any one can obtain these by study, always allowing that they have the feeling and taste for nature and art to begin with as a foundation; and people will soon begin to see that, in the rendering of the effects of nature, photography has in many cases no equal; artists will take it up and make it the handmaid to painting, and with its truthful power and delicate sensitiveness, it can be of the greatest assistance to them; for whatever effects may be chosen as subjects for painting, Nature, in the first instance, must be taken as the guide; photography can imitate Nature as *truthfully* as it is possible without colour, and truth is everything. It has ever been, and ever will be,

Magna est veritas, et praevalabit.

JOTTINGS FROM THE NOTE-BOOK OF A "PHOTOGRAPHER'S ASSISTANT."

No. III.

THE USE OF NITRATE OF SODA IN THE PRINTING BATH.

THE subject selected for this, our third "jotting" is one that demands the serious attention of every professional photographer, for an adoption of the modified formula for sensitizing albumen papers, we are about to propose. Whilst improving pictorial results, it will confer pecuniary advantages, which of itself is sufficient to render it worthy of something more than a passing consideration, as a saving of something like 75 per cent. will be effected in the consumption of that expensive material, viz., nitrate of silver.

The necessity for the employment of a strong nitrate bath has always been imperatively urged by every writer on photographic printing, and the reasons advanced invariably tend towards one point, viz., the coagulating influence exercised by the nitrate salt upon the albumenized surface of the paper. To enter fully into this interesting subject would require more time than we have at command; our remarks must, therefore, of necessity be brief; but we hope the arguments we are about to advance will sufficiently prove the second point named for discussion in the present paper:—The unscientific and expensively wasteful method adopted for producing coagulation (so called). We say "unscientific," because science, when genuine, aims at

simplicity, combined with the strictest economy, and every law of nature teaches that the greatest success is attained when the smallest amount of material is judiciously employed.

The appearance of albumen, as obtained pure from the egg, is familiar to every person; but the change this substance undergoes during the process of spontaneous drying does not appear to be so generally understood, as there are many intelligent writers on the subject who still entertain a belief that dried albumen is coagulated when exposed to a high temperature or to the action of certain metallic salts. The effect named is certainly produced when albumen undried is the substance experimented on; but we are inclined strongly to believe that during the process of drying its properties undergo a peculiar change, not merely by a modification in its molecular arrangements, but from a naturally produced separation of its life-yielding principle which, once removed, cannot by any means be restored; and with the loss of this substance the albumen loses all tendency for coagulative change. When exposed to the action of silver in solution, in obedience to the laws of chemical affinity, a combination ensues, the results of which is the production of an organic compound known as the albuminate of silver, in which condition the properties originally found in the albumen are altogether lost. The soluble tendencies no longer exist; but it must be remembered that the insoluble conditions are not perfected until the chemical change is entirely effected; hence the necessity for producing the union before the water has exercised its solvent influence to a perceptible extent. Where silver alone is employed, if the solution is at all weak, the horny surface of the albumen, before it can effect a union with the metal, is partially dissolved by the solvent influence brought to bear on it by the water. It is, therefore, necessary that a liberal allowance of the metallic salt be provided, in order that the resistance might be quickly overcome, which modifies the evil to a great and beneficial extent, so far as results are concerned. But the cost renders it doubtful whether the advantages are not too dearly purchased, because there is so much uncertainty in the matter for the following reasons:—Every sheet of paper floated withdraws from the solution a certain quantity of silver; consequently, the bath becomes more powerful in its solvent action on the freshly produced albumen. To prevent this, the method adopted is to add an occasional dose of strong silver solution, which prevents what it cannot effectually cure. This style of doctoring is not merely expensive, but wasteful, as a large portion of the valuable salt is lost during the tediously prolonged washings its presence renders requisite; and, in addition to this, the free nitrate borne on the surface of the print to the toning bath assists materially to produce the dreaded mealiness.

The foregoing arguments will be supported by the remarks we now offer in favour of a salt whose peculiar properties, when known, will secure for it a prominent place in every printing laboratory. The salt referred to is nitrate of soda.

The influence exercised by this salt would appear somewhat paradoxical if, in experimenting, we lose sight of the difference that exists between pure dried albumen and albumen in combination with silver. The first-named substance, when exposed to the action of a nitrate of soda solution, is completely dissolved, so that the paper has no remaining trace of it left on its surface; but when the last-named combination is subjected to the same conditions, the results are quite different; not the slightest change, neither in weight nor colour, has been effected, nor has its brilliancy been tarnished to the smallest degree. What does this prove? Why, that albuminate of silver is insoluble in a nitrate of soda solution; also, that its solvent influence on pure albumen might be made useful, as it combines mechanically with silver, assisting rather than interfering with its duties. The obstruction offered by albumen is purely of a mechanical character. Its atoms must be loosened ere the silver can gain access to them. The quicker this is effected, the sooner

will the union ensue, because the affinity is powerful in its nature. The nitrate of soda loosens the atoms referred to, but before they are separated the silver unites and an insoluble substance is formed. This explanation, wild or improbable as it may appear, may be tested by a few simple experiments.

Make an 80-grain solution of nitrate of soda, on the surface of which float a piece of albumenized paper; when dried, no trace of albumen will remain.

2nd. Float another piece of paper on an ordinary silver solution; dry, and float a second time upon the soda bath; when dried, the surface will appear as perfect as before.

3rd. Take a piece of paper that has been floated in the silver bath, and place its sensitized surface on pure water; dry, and expose with the last to light; that submitted to the soda bath will colour vigorously, whilst the other will be insensitive, and colour sparingly.

4th. Excite a piece of paper on a 35-grain silver solution; dry. Now add to each ounce of the above 80 grains of nitrate of soda. Float another portion of the same sheet of paper; dry; then compare results, both in appearance and printing properties, when it will be found that in both respects the last portion of paper experimented on will be infinitely superior to either of those sensitized under the conditions present in the other experiments. And now it remains to test whether the improvement is produced by any chemical combination between the albumen and soda.

Sensitize a portion of paper; dry, and weigh carefully. Now float on the soda solution, dry, and weigh it a second time, when it will be found that no addition has been gained or loss of weight sustained.

There is yet another advantage gained by the use of the salt whose claims we advocate; in addition to the saving effected, its use will decrease to a considerable extent the proneness of some papers to mealiness, loosening the atoms of albumen in the manner we have described, will enable the silver to penetrate to greater depths, and the bleaching power of ordinarily constructed toning baths will have more substance on which to exercise their devouring appetites. To those who use india-rubber or enamelled papers, we strongly recommend the nitrate of soda: the papers named are very slightly coated with albumen, so that to attain good results the slightest portion of the last named substance cannot be spared; for, except the picture is formed on the albumen, toning to a satisfactory colour will simply be an impossibility. In concluding the present paper we name the proportion which experience has proved to be best. Nitrate of soda, 80 grains; nitrate of silver, not less than 35 grains per ounce; a practiced eye is necessary to distinguish a deficiency of either salt, but as the soda wastes but little, any weakness in the appearance of the print may generally be remedied by an addition of silver in small quantities. Before laying down our pen, we would just add one remark, as it will be seen that we pretend to introduce here nothing new, save an attempt to reduce the operation of sensitizing to something like system; for, whether we work out an original idea, or introduce the suggestions of others, except system attends our undertakings, success and failure must remain trembling in the uncertain balance of Chance.

PHOTOLITHOGRAPHY.

BY JOSEPH LEWIS.

No. IV.

VARIOUS METHODS OF PRODUCING AN IMAGE ON STONE.

THE Lithographic principle is so purely chemical, that any means of effectually carrying out by that process the printing of the photographic image must depend more or less upon the same laws. It is worthy of remark that there is scarcely a photographic process but may, by sensible dexterity, be turned into a means of producing a lithographic printing surface. To produce a printing plate or block, a large amount of material must either be taken away or added, so as to alter the figure or level of the surface. With lithography it is dif-

ferent, the slightest film of grease or gum produce either a black or white result on the stone. The power possessed by light and air to decompose a greasy substance, producing a film insoluble in the hydrocarbons, as we have seen in the transfer process described at page 403, furnishes a ready means of securing the proper deposit of fatty matter on the stone to produce a printing foundation. I come now to consider another process, the converse of that above alluded to, both of which come under the second head in our classification.

I have already stated that the stone is so exceedingly porous and absorptive that it is difficult to dislodge any substance if once imbibed by it; yet there are means within reach of indirectly effecting that purpose, as in the following process. (2) I take a clean stone and spread over it a thin film of saliva or very dilute isinglass; when dry I coat it evenly by means of a composition roller with the preparation of bitumen, suet, &c., described at page 403; when the film has become hardened, the negative may be applied and exposed for several hours according to the intensity of the light. A mixture consisting of turpentine, 4 oz.; a few drops of nut oil, also of bisulphuret of carbon, are to be added; to these I put an equal volume of thin gum water, and shake well together, the negative being removed; the stone is covered with this mixture and gently rubbed with a soft sponge, adding printing ink to charge the work; by this means the image is gradually developed and prepared for printing. The features of novelty in this process consist, first, in the primary preservative preparation of the stone by saliva or other similar neutral substance, whereby the sensitive and oleaginous ingredients are prevented from penetrating the stone until they are *changed* by light; second, the combining proportions of the alkaline bichromate with the resin and the fat, so that by the oxidizing influence exercised by light and air they become saponified, and in that condition are able to permeate or corrode the saliva film, thence into the stone. Ordinary printing ink cannot penetrate a thin film of gum or isinglass; but if soap or an alkali be added, it does so readily.*

Third, the nature of the solvent employed, the peculiar manner of using it, by mixing the gum water with the turpentine, &c. The addition of the gum water and oil to the turpentine causes a film of grease to deposit upon the insoluble parts that would be effectually washed away, if turpentine only was applied.

(3.) The stone in this case is rendered more effectually non-absorbent either by an etching with gum and acid, or, what is better, by an alkaline solution of silica, to be more particularly described hereafter. This being effected, it is evenly coated with a solution of bitumen in bisulphuret of carbon, to which a very small quantity of Canada balsam has been added. Upon this a reversed positive is placed, and after exposure for several hours in good light it is to be washed in a mixture of bisulphuret of carbon and turpentine, equal quantities. The fixing being effected, the stone is washed over with a solution of alum or acetic acid, which possess the quality of decomposing the non-absorbent coating on the stone, and so prepare it in those portions where it has been left bare by the solvents for the reception of the printing ink.

LACTATE OF SILVER FOR THE BATH, AND LACTATE OF IRON FOR THE DEVELOPING SOLUTION.

BY M. MC A. GAUDIN.

I AT first prepared lactate of silver, by the action of lactic acid upon oxide of silver, but did not succeed by this method,

* By the practical application of this fact, when the penny postage stamp was introduced, I proved the inefficient nature of the obliteration mark, having coated a Queen's head (then printed in black ink) with a thin coating of made starch. The letter was posted and obliterated in the usual course. My confederate, to whom the letter was addressed, received it, and in presence of the postman washed off the obliteration by a single application of his wetted finger. By this means the same stamp may be used perpetually, and by the same principle the transfer process of Mr. Osborne and Colonel James are effected.

as it was a black mud, of which it was impossible to make any use. I succeeded better by making lactic acid react upon *carbonate of silver*. After filtration through paper, we obtain a yellow liquid with excess of lactic acid, but this bath is much too reducible; it must be largely acidulated with nitric acid: even by using this corrective, we do not attain to the sensibility of the ordinary nitrate of silver bath, which I had hoped to be able to surpass. But this bath of lactate of silver possesses a peculiar property; it can be employed very *weak*, without letting the sensitive film detract itself from the plate, as with the ordinary nitrate of silver bath, under the same circumstances; and moreover, *it does not dissolve the iodide of silver*: so that there is no fear of its forming spots, in consequence of its concentration by evaporation, as always occurs with the bath of nitrate of silver, however short a time the sensitized plate remains in the slide. With this lactate bath, the sensitized plate may probably remain out of the bath an hour without injury. This, however, remains to be proved. On the other hand, lactate of silver is constantly undergoing modification with time. At the end of four-and-twenty hours, it becomes of an intense yellow colour, and requires a fresh addition of nitric acid to work with.

As to the lactate of iron for a developer, it requires an addition of sulphuric acid to fit it for use. The negatives it yields are exceedingly fine, analogous to those obtained through pyrogallic acid; they are blue by reflected light, and red by transparency, like those developed by protoacetate of iron, but the whites never come pure.—*La Lumière*.

IODIDE OF SILVER IN COLLODION.

BY M. MC. A. GAUDIN.

WE may introduce as much iodide of silver in suspension into collodion as we think proper, *without fear of fogging the pictures by leaving the collodion in the light, or in pouring the collodion on to the plates in the open air*. The presence of the iodide in solution in collodion renders this iodide of silver absolutely insensible to luminous radiation, and is therefore an excellent means of augmenting the porosity of the collodion which remains opaline after being filtered through the most compact cotton. I have not yet satisfied myself if the collodion gains in sensibility; and here perhaps an obstacle presents itself. Sensitized collodion is as impenetrable to actinic rays as orange yellow glass, although its hue is much paler; in this particular it is superior to bright yellow paper, so that in reality sensitized collodion is attacked by a strong light only, at its surface on account of the colour of its particles; it is on this account that there will be more advantage in introducing some bromide, chloride, or cyanide of silver, which are perfectly white, into the collodion, than in introducing iodide of silver in suspension, so that the perfection of collodion will very probably come to consist in a combination which will admit of a soluble iodide in very minute proportions, sufficient only to guarantee the argentiferous compound in suspension from every attack of light, and to form at the moment of its sensitizing the iodide of silver necessary to commence the attack under the influence of the least actinic action.—*La Lumière*.

OXIDE OF SILVER PRINTS.

BY F. F. THOMPSON.*

PREVIOUS to the removal of my "Den," a few months ago, I made a few very satisfactory prints by the oxide of silver process, and was so pleased with it that I am determined to adopt it in my future operations. I hope at the next regular exchange to send the club prints made with only fifteen grains of silver to the ounce of water in the floating bath.

The process is thus:—

Nitrate of ammonia	3 ounces.
Filtered water	10 "

* *Amateur Photographic Print.*

Shake up; and when thoroughly dissolved, add moist oxide of silver to saturation.

The moist oxide is made by adding to a pint of 20-grain solution of nitrate of silver, caustic potash, till all the oxide is thrown down. Wash the precipitate clean from all traces of potash, and put it while wet in the nitrate of ammonia solution. There will settle to the bottom the surplus of oxide of silver, which serves both to keep the bath saturated and clear.

Add three drops of nitric acid to each ounce, and sensitize the paper by floating half a minute. After the paper is dry, fume it with ammonia in the usual way, and print as ordinary. Should the albumen dissolve in the floating bath, then add more nitric acid to the bath, and fume for a few minutes longer.

A NEW METHOD OF ASCERTAINING THE ANGLE OF APERTURE OF A LENS.*

IN the first place, it is necessary to have the expression "angular aperture" so defined that the teacher and student may understand each other. The angle of aperture of a lens or combination is that angle which is bounded by those external rays of the maximum pencil which, after refraction, is brought to one and the same focus on the other side of the lens or combination.

The opening of a lens or combination is the amount of surface exposed, and is measured by the angle formed by lines drawn from the centre of the object to the periphery of the glass surface.

Let PTGLHSN be a double convex lens, ABC the object,

and DEF the picture of the object. The axes of the radiant points A, B, and C will be BOE, AOD, and COF. Now if BG and BH are the limits of the largest pencil that can be transmitted through the lens and brought to one and the same focus, E, then GBH will be the *angle of aperture*; and that part of the surface of the lens comprehended by the arc GLH is all that is required for effective work, or all that is available in producing clear definition; for supposing the lens to extend on either side as far as T and S, the rays TB and BS will be the boundaries of the conical pencil from the radiant B; but these rays after refraction are brought to a focus at I, and all intermediate rays between TG on one side, and HS on the other, will cross after refraction on the axis between E and I, and produce, in connection with the oblique pencils, a blur or haze, on the central part of the picture, which is commonly denominated the *ghost*.† This ghost will always be visible on pictures produced by lenses that are not thoroughly corrected for spherical aberration, or in which there is an excess of surface exposed over and above that which is required for the transmission of the largest pencil that can be refracted to one point.

Thus, then, the surface or arc TGLHS is the *opening of*

* From *Humphrey's Journal*.

† Other causes conduce to produce the *ghost*, which I will explain in a subsequent article.

the lens; but the parts TG and HS tend to produce the ghost, both with the direct and oblique pencils, and are detrimental to the lens, and consequently altogether unnecessary. Now the angle TBS represents the angle of the opening of the lens, but it is not the angle of aperture which measures the *defining power* of the lens.

By peculiarities in lenticular combinations—which can be calculated mathematically—two lenses may have exactly the same magnifying power, and yet be quite different in regard to angular aperture, and, consequently, varying in optical value to the ratio of the superior angular aperture; for the lens with a large angular aperture transmits a large pencil of light, and thus produces a very brilliant picture, whose parts are more easily designated, whether applied to microscopy or photography.

We see at once, then, the absurdity of regarding the illuminated circle or picture on the ground glass of the camera as a criterion by which to judge of the value of the lens, as long as this illuminated circle is not equally sharply defined from the centre of the periphery. If on the contrary, however, every part is equally sharp, then this circle becomes the base of the cone whose sides bound the angular aperture.

A thoroughly corrected lens, whose angular aperture is of the same size as the lenticular opening, is recognized in the following manner:—Place the camera on the camera-stand and focus an object, as, for instance, a church steeple, whose base is in the centre of the circle and the spire in the periphery; focus the central part perfectly sharp; the spire will also be sharp if the correction is perfect. Or move the camera to the right or left so that the base of the church steeple is visible on the peripheral parts of the circle; if it is still in focus and sharp, the lens is correct. But most lenses will not bear this rude ordeal. Like many individuals attired in gorgeous apparel, the vesture is no criterion of the man; nor is the *size* of the illuminated circle a test of the value of a lens.

The result, in either case, is the same, namely, an equally sharp picture from the centre to the edge.

This picture, then, is the base of a cone whose sides bound the angular aperture, or working power of the lens, and this angle we wish to measure.

We will suppose, however, that the circular picture of a landscape, for instance, with a given lens is not equally sharp upon the whole surface—what is to be done?

Put in the smallest stop and then examine.

Supposing by this expedient the error is not thoroughly corrected—what next?

Elongate the cylindrical tube in front of the lens so as to exclude oblique rays, and examine once more. By this expedient the illuminated circle will gradually be diminished as the elongation is increased, and the picture will receive an increase of sharpness.

We will finally suppose that the error is not yet thoroughly removed—what is our next step?

To diminish the opening of the lens by means of stops immediately in front of it, as well as to apply the elongated cylindrical tube so as to shut out oblique rays, until finally a small sharp picture is obtained that is regarded as in every respect satisfactory.

The picture so obtained is a part of the panorama before you; it is, however, in the form of a circle, and has to be cut down into the form of a square. Knowing the diameter of the illuminated circle we can easily calculate the side of the inscribed square, which is equal to the square root of twice the square of the radius of the circle.

Place the camera-stand on an open plain, or on the flat roof of the tower of a church, etc.; level the platform and insert the camera between the ledges; it is evident that, when so placed, the axis of the lens divides the horizon into two semi-circles of 180° each. We propose, therefore, to compare the semi-circle with the angular width of the square picture.

To do this we focus the landscape and observe very care-

fully so as to recognize some object on the left side of the illuminated circle. As soon as this is done, keeping the object all the time in view, we move the camera carefully so as not to disturb the position of the camera-stand, until the object that was originally on the left side of the picture is now on the limit of the right side. Reckoning from the axis of the lens when we started to the limit of the picture now, we have taken in one circle and a half of the panorama on the ground glass. Fixing your eye again upon an object on the left, move the camera to the right until this object is seen on the right-hand limit; we have now two circles and a half from the starting point. Proceed in this way until the camera has been completely reversed on the stand, and ascertain the number of circular pictures and parts of a picture that are comprehended in the hemisphere. This number, whatever it may be, is the divisor, and 180° the dividend; the quotient will be the angular aperture of the lens.

Supposing the circles and parts of circles added together make three and nine-tenths, then 180 degrees, divided by three and nine-tenths, will give 46 degrees, 9 minutes, and 13 seconds for the circular angular aperture of the lens so tested.

One of Harrison's globe lenses for stereoscopic purposes thus tested—assuming the circular picture to be equally sharp to the edges with oblique rays, which is certainly not the case—gave a circular angular aperture of about 60 degrees, which, when cut down to the panoramic square, will be about 42 degrees.

We do not speak (with any preconceived idea) in disparagement of the globe lenses; we are of opinion, however, that, inasmuch as the illuminated circular picture is much larger than required for stereoscopic purposes, and not quite sharp to the edges, it would be a decided improvement to furnish the tubes with cylindrical prolongations in front, so as to shut out a quantity of oblique rays that tend to destroy the uniformity of the illumination.

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE first meeting of the winter session was held in the City of London College, Leadenhall Street, on the evening of Thursday, September 8th, the Rev. F. F. Statham, M.A., F.G.S., in the chair.

The minutes of a former meeting having been read and confirmed, the following gentlemen were elected members of the Society: Messrs. May, Auther, and A. H. Wardlow.

After regretting that a misunderstanding regarding the announcements had issued in a failure of the out-door meetings this summer, the Secretary called the attention of members to the fact, that subscriptions were now due, and should be paid not later than the next meeting night; members wishing to forward them, might do so to the Treasurer, Mr. Noel E. Fitch, 13, Union Street, Borough.

Mr. WALL brought for the inspection of members, a drawing in black and white chalk, with a gold background in the mediæval style, by Mr. Reijlander, being a copy of his recent photograph of Tennyson. The drawing was very severe, round and forcible, and exceedingly truthful. It illustrated one use of photographs to the artist, who might, from two or three imperfect prints, produce a drawing equal to one perfect photograph, with other added qualities which he might desire. In this instance, in addition to the properly printed photograph for general effect, a darker copy had been taken to get the drawing in the lights, and a light copy to secure detail in the shadows. A perfect photograph possesses, of course, perfect light and shadows, connected with the duo gradations of half-tone in each, all in their proper relation, but in producing something for the painter to copy or paint from, it is sometimes desirable to produce copies slightly exaggerating parts, such as the detail in lights and shadows, to render them more obvious.

Mr. WALL also exhibited a fine reduced copy of Reijlander's "Two Ways of Life," and some prints by the same gentleman as illustrations of the power of photography to render expression; also a burlesque photograph in which the effect of Millais'

"Eve of St. Agnes" was imitated by a young woman engaged in what is known in the laundry as "dollying." He also called attention to a very fine solar camera picture by Mr. Sidney Smith, produced on tinted drawing paper, and very effective.

Mr. WHARTON SIMPSON exhibited a charming subject picture by Mr. H. P. Robinson, entitled "Somebody Coming." A pretty little rustic girl, sitting at a stile, looks archly round to tell another older companion that somebody is coming, whilst the half-averted and coy face of the elder girl plainly indicates her feelings to that "somebody." The picture is from one negative, 12 by 10, is exquisitely round and soft, and was pointed out as a fine illustration of the qualities of Blauchard's bromo-iodized collodion. Mr. Simpson also exhibited a very handsome album, got up by Messrs. Marion purposely for Mr. Wilson's album pictures, which are about 4½ inches by 3 inches. The album was filled with fine specimens of Mr. Wilson's recent labours, some of which were cleverly coloured. He also exhibited an album with some fine card pictures of Irish scenery by Dr. Hemphill. Mr. Simpson also showed a moonlight negative by Lieut. Noverre, containing the moon, moonlit clouds, and the traces of a landscape and foliage. When prints merely were shown, he observed, it was easy to suspect that some dodging or trick might have been practised. But here was the negative; the moon sufficiently defined to give its markings, together with the other objects he had just mentioned, a practical answer to those gentlemen who had pronounced the thing impossible. The negative was taken with Dallmeyer's No. 2 Triple lens, full aperture, bromo-iodized collodion and iron development: exposure about 20 seconds.

Mr. ALFRED HARMAN exhibited a very fine print from an enlarged negative.

Mr. HOWARD showed some good pictures by the Fothergill process.

Mr. HARMER exhibited some interesting specimens of his success in transferring the albumen film to opal glass.

Mr. BLANCHARD showed some exceedingly perfect pictures, consisting of whole-plate studies, to show the qualities of his collodion with simple iron development.

Mr. JABEZ HUGHES showed some charming card pictures of the Princess Louise and others.

The CHAIRMAN showed some cards he had purchased in Italy, and a print with several medallion heads, by Mr. Dean.

Mr. WALL then read an opening paper entitled, "A Few Thoughts about Photographic Societies." (See p. 486.)

The CHAIRMAN in proposing a vote of thanks, remarked that Mr. Wall's remarks on the dearth of practical papers was illustrated by the fact that he had been driven to photograph the societies themselves.

Mr. HOWARD agreed with Mr. Wall on the subject of Exhibitions. They ought not to be regarded from a monetary point of view, and he thought the funds of societies could not be more properly spent than in promoting exhibitions; and charging exhibitors for space appeared something like a trading speculation. If there were no funds, it might be another question. Regarding the light estimation photographs received from the public, one reason was, he thought, the ease with which something, however poor, might be produced. As all kinds of appliances continued to improve, so would photographs, and they might eventually command a higher position. He thought too, that the present method of toning and fixing, tending as it did to greater permanency, would elevate the art.

Mr. SIMPSON in reply to a question from the chairman, said he had no especial remark to make upon the paper, the greater part of which would, he thought, command general assent. There was one part of it, however, to which he must take exception; and whilst he did so, he would deprecate all further discussion of it at that meeting. He referred to the observations on Photographic Societies charging non-members for exhibiting space. The fact that the Photographic Society of London, generally spoken of as the parent society, had only a few weeks ago announced that, in future exhibitions, they must make such a charge, gave Mr. Wall's general remarks a definite and specific bearing; and he thought it would be very bad taste indeed, for another society to discuss the matter at all. If they were themselves contemplating holding an exhibition, there would be some reason for discussing the question; as it was, it came before them *à propos* of nothing, and appeared very like meddling with what did not concern them.

Mr. WALL said he had, at the commencement of his paper, guarded himself from particular applications, by stating that

his remarks had only a general bearing. He thought that it was quite a legitimate subject of discussion.

Mr. SIMPSON still must deny that it was either a legitimate subject for them, or that it could be discussed generally. It was a subject which could not be discussed without relation to circumstances, and the recent announcement of the parent society gave it at once a personal bearing.

The CHAIRMAN suggested, that if any further remark were made on the subject, care should be used to avoid personal or specific allusion.

Mr. JABEZ HUGHES thought it impossible to enter into the subject at all, without being personal, and he must protest against this society discussing the subject, as it could not be considered in the abstract. They could not then enter into the reasons which had induced the parent society to take such a course, which, probably, was necessary; but at present, and for this society, he thought it wisest to hold their tongues, and say nothing at all. Regarding the paper generally, he thought, perhaps, Mr. Wall had scarcely done justice to the great good which photographic societies had effected. He believed that the position of photography at the present day was largely due to societies. Without photographic societies and photographic meetings, photography could not have advanced so rapidly and so certainly as it had done. Perhaps no better illustration could be given than the history of alkaline gold toning. Without photographic societies and photographic journals, such an improvement could not possibly have reached photographers so rapidly. By means of societies, it not only reached photographers rapidly, but its results were shown, and by their means, and the impetus given by Mr. Hardwich, the process was disseminated and accepted at once and photographers generally were now deriving the benefit. Another illustration might be found in the history of bromo-iodized collodion. Without societies and journals, it was probable that a knowledge of its value would have been kept as a kind of trade secret, known to one or two persons, whilst other photographers would have constantly wondered at the superior softness, delicacy, and clearness of their pictures; and photography generally could not have held the position it now held. He might, moreover, point to the improved artistic state of photography, as being largely due to the action of this South London Society, and Mr. Wall, as its secretary, in calling attention to the artistic deficiencies of photographers, and to the abominations, now almost passed away, of white paper skies. Whilst, then, aiming at improvement in societies, he thought they should never forget how much they had already effected.

Mr. WALL said, it was because societies had done so much good, that he wished to see them assume a character which promised stability. Many useful societies were dead, having died out for want of being established on a better and more permanent basis.

After some conversation on the possibility of promoting social meetings amongst photographers, or of establishing something like a club, and on some other subjects, it was announced that Mr. Warner would contribute for the next meeting a paper on photography in India and warm climates; that Mr. A. Harman would bring some illustrations of the effect produced by light and heavy salting of albumenized paper, and that Mr. Hart would bring some instruments to facilitate accurate estimation of the amount of silver or gold salts in given solutions.

The proceedings then terminated.

Correspondence.

TRANSFERRED ALBUMEN FILMS.

DEAR SIR,—Can you or any of your correspondents inform me how to make or procure a good opal varnish? Perhaps I ought to state the use I wish to make of it. It is this—to coat a curved glass with it, either before or after an albumen film has been transferred on to it (the glass) by the new process, as I think that for brooches, &c., photo-diaphanic will prove almost invaluable.

In the comparatively few experiments I have made with this process, I have found that, upon removing the print from the hypo, the surface on no account should be touched,

as the film is so exceedingly tender that it is sure to tear if meddled with; and when the print has been trimmed to the proper shape, of course it is spoiled by the least tearing or abrasion of the edge. The best way to remove it is to slip a plate of glass underneath. As soon as the print is placed in water, the film separates; it must now be left untouched for about half an hour, when it will have become tough, and may be carefully handled. The larger the quantity of water into which the print is first placed, the better. I only made these notes for the benefit of those who are about to make their first attempt in this exceedingly elegant and fascinating process. Another thing that I found tiresome at first was the thorough washing of the film, which is absolutely necessary.

The following was the most successful method:—Have ready several large basins filled with water, one more than the number of prints to be transferred. Upon removing from the hypo (in which no more prints must be fixed at a time than will lay at the bottom of the dish without touching each other), place *one print* in each basin, and, for the reason previously mentioned allow them to remain half an hour. Now have a dish of requisite size—if the print be very small, a saucer will do—and with it remove one of the films into the basin containing clear water. Fill the basin from which it was removed with fresh water, and place one of the other films in it, and so on, till they all are thoroughly washed. Care must be taken not to pull the film too tightly across the article on which it is placed, or else, upon drying, it will be found to be full of minute cracks. This inconvenience will also be experienced if the film be not sufficiently washed.

I give warning to all those who have not tried this process, that a great deal of patience will be required to bring it to a successful termination. I should like to see some fidgety, testy, old gentleman trying to catch a film in the right position on a curved piece of glass!

Amateurs are sure to have several friends who think there is no trouble involved in photographic operations; it would be a capital plan to set them at photo-diaphanig; they would soon discover their mistake. By the bye, that reminds me that if, when the film is dry, you find it is not exactly in the position required, the best means to remove it are to place the article whereon it is in a vessel containing warm water (about 120°), and allow it to remain till it separates, when it may be caught again.

I have found the addition of a little alcohol to the nitrate bath to be of great service in many ways.

Some persons, upon reading these remarks, will, I dare say, exclaim that I have wasted a good deal of your valuable space upon trifling details, that every one, with any common sense, might find out for himself. My excuse, if any be required, is this—that it ought to be the endeavour of every photographer to save his brethren, who are about to try a new process, from failure, by describing the most trivial points of danger, as nothing is more disheartening to the novice than to find everything go right up to a certain point, and then a failure to occur from circumstances which the originators of the process have thought too unimportant to mention.

Many valuable formulæ have, doubtless, been discarded from failure in the first instance, when, if more minute directions had been given, the primary success would have encouraged in any subsequent mishaps.—I am, dear Sir, yours truly,

H. COOPER, Jun.

5, Aberdeen Park, October 12, 1863.

MICROSCOPIC CAMERA.

SIR,—I was prevented noticing Mr. Eden's letter in reply. He admits, clearly, that Mr. Potter first made the instrument he claims as his patent, but adds, that with it I could not produce good pictures—meaning to convey the impression that the instrument was not right for the purpose. The fact is, the instrument *did* answer admirably, and so long as the collodion I obtained from Mr. Willis was right,

I did take good pictures with the greatest ease, and many of them too; but my collodion got wrong, by some means which I could never discover or explain, and then, only, did I meet with difficulty—not in taking them, but in producing a fine deposit of silver, so as not to look coarse under the microscope; and not being sufficiently well versed in photography, nor caring very much about it, I gave up, after several attempts.

I have a recent letter in my possession, from Mr. Willis, in which he tells me, that the addition of the mirror and dark frame was suggested to Mr. Eden by himself, when in York.

Apologising for thus troubling you with this, my final communication on the subject, I remain, Sir, yours truly,
Manchester, Oct. 12, 1863. J. CASARTELLI.

Photographic Notes and Queries.

GOLD TONING.

SIR,—Constantly reading about, and frequently experiencing difficulties in the way of uniform results in connection with, gold toning, it occurred to us that any remarks concerning experiments in that direction might be acceptable to many of your numerous readers. We have therefore inflicted this short letter upon you, not to advance anything new, but to give our opinion of one or two methods of toning which have lately appeared in the NEWS.

When we read of the tones produced by Parkinson's method, we tried it, and found it a great improvement on the old bicarbonate of soda and gold process; there was *no greater* tendency to meadiness, quite as much certainty in action, and much more beautiful results; yet we were not quite satisfied with it, as two baths prepared by the same formula and of the same age frequently did not work alike, resulting principally, I should imagine, from difference in the quality of the chlorido of lime. The formula I here allude to is,—

Chloride of lime	45 grains
Carbonate of lime	75 "
Chloride of gold	15 "
Water	6 pints

used about a week old.

In No. 262 of the current Vol. of the NEWS, however, Mr. Parkinson gave us another formula, in which acetate of soda plays an important part. We have tried it and *are quite in love with it*; we have never had one failure, the tones are all we desire, the bath keeps well and is very economical. I enclose a print toned by this process; please give your opinion of it.—We are, Sir, yours faithfully, BELL & FREEMAN.

P.S.—On Monday last—that is, the day preceding the night on [which] shocks of an earthquake seem to have been felt, more or less, all over England—during the early part of the afternoon, while there was apparently plenty of light, it was almost entirely deficient in *chemical rays*, as six or eight times the ordinary exposure *did not* suffice for a portrait.

Photographic Dépôt, Newcastle, Staffordshire.

October 8th, 1863.

[The print is very good.—Ed.]

ROUGHING THE EDGES OF GLASS.

DEAR SIR,—Several suggestions have appeared, from time to time, as to the mode of roughening the edges of glasses, but the plan I have had in use for some years past is, in my humble opinion, superior to any of them; and with the idea that it may be acceptable to some of your readers, I send you an account of it.

The material I use is corundum, and in the form of a corundum file. Before proceeding, I must, out of consideration to you, as it holds no relation to the editorial file, explain the meaning of this technical term, otherwise I should bring down upon you an avalanche of letters, each containing the pertinent inquiry, "What is a corundum file?"

Of corundum it is sufficient to say that it is a mineral spar, of great hardness and cutting quality, which, when mixed with melted shellac, or some such cement, and moulded on to a slip of iron, which serves as a core to the paste, constitutes the corundum file used by dentists, and sold at the dental dépôts.

I have extemporized a similar tool for photographic purposes, by cementing to a slip of glass, bits of waste corundum wheels,

which is the same compound in the form of a grindstone. As, however, few photographers have the chance of making such a thing for themselves, I have no doubt there would be a good sale for an article of this kind, if some of the dealers would bring it into the market. I would suggest a piece of sheet iron or glass, four inches long, and one inch, or so, wide, coated on both sides with the composition to a thickness corresponding to the width of the surface required to be ground, say $\frac{1}{4}$ th of an inch. The manner of using it will, I think, be obvious; the slip, moistened with water, being applied to the edge of the glass, which may conveniently be placed in a glass-cleaning vice, with the edge projecting, by a horizontal motion, the edge of the corundum grinds the surface of the glass; the core, serving as a guide at the same time, just taking off the cutting edges.—Yours, truly,
GEO. S. PENNY.

[We have used corundum, for the purpose mentioned, with great success, and we fancy we have seen it in the shops of some of the dealers. It deserves to be better known.—ED.]

Talk in the Studio.

THE EARTHQUAKE.—The records at the Observatory, at Greenwich, are thus stated:—"At 23 minutes past 3 o'clock, on Tuesday morning, a slight shock of an earthquake was felt. One of the Astronomical Assistants was observing a fixed collimator, and saw the mark apparently descend through an angle of less than a quarter of a minute of arc, and rise again after a few seconds of time to its former position. No trace of the earthquake was left on the photographic records of the self-registering magnetometers."

ROYAL PHOTOGRAPHS.—The Princess of Wales, the Princess Christian of Denmark, and Princess Dagmar, attended by the Hon. Mrs. W. Grey, again honoured the Messrs. Southwell, in Baker Street, with a visit, and sat for their photographs, on Tuesday last.

To Correspondents.

* * * Current numbers, or full value, given at this office for Numbers 6, 9, 41, 49, 53, 65, 76, 80, 104, of the PHOTOGRAPHIC NEWS.

YOUNG PHOTOGRAPHERS.—Silvery white tones in glass positives are best obtained by using a developer of protosulphate of iron instead of protosulphate. We have often given the formula, but we repeat it again. Take—
Nitrate of baryta 1 ounce
Nitric acid 2 drachms
Water 16 ounces.

Mix and dissolve, and then add—
Protosulphate of iron 1½ ounce.

Let it stand a few hours and then filter to remove the white precipitate, and the solution is ready for use. 2. The use of a newly-mixed solution of sulphate of iron with insufficient acid, or the presence of organic matter in the bath. 3. We do not quite understand the nature of the defect to which you refer; from your description, it is probably caused by floating scum on the bath. 4. A line across the film most commonly arises from a stoppage whilst immersing the plate. 5. A transparent mark at one end or round the edges arises from the partial drying of the film, leaving the part insensitive because impermeable. 6. An over-exposed picture developed rapidly is less apt to be fogged than an under-exposed picture developed slowly and forced in development; but a properly exposed one will give the best result. 7. To avoid too much light on the hair without making the face dark, use less top-light. 8. When there is a shadow in the upper portion of the background, bring it a little further forward to the light.

W. A. S.—In using a second nitrate bath there is no necessity for washing the plate. See article in our number for August 14th. Re-dipping after exposure, except in a bath in perfectly good condition, is apt to cause fog; it is the condition of the free silver which is of the greatest importance. Boiling down and precipitating are both troublesome methods, and should only be adopted when other methods fail.

CAMERA LUCIDA.—You will find some information relative to the building of glass rooms, in No. 59 of the PHOTOGRAPHIC NEWS; and on the best form and general arrangements in our last year's ALMANAC. Mr. Blanchard's design is in No. 249, and Mr. Rejlander's and Mr. Sutton's in No. 235. The top of a house is preferable, if there be surrounding buildings to cut off the light from the garden; but not otherwise. The proportion of glass depends on circumstances. See the article in our ALMANAC.

NOTICE.—To use nitrate glue, first heat the portions of glass, &c., to be joined, and then apply the glue to a flame to melt it, taking care not to burn it. Or it may be made hot in an iron spoon or larger vessel, and applied with a brush. It is not dissolved like common glue. 2. We believe that Mr. Solomon, Bull Brothers, and others whose names you will find in our advertising columns, will supply the papier mache ornaments for accessories. 3. The addition of alcohol to the developer is simply to make it flow more easily. It does not affect the character of the development at all. It is only necessary where the silver bath has accumulated a large amount of ether and alcohol.

EMBOSSED.—Red spots occurring whilst toning, arise from imperfect action of the toning solution on the parts in question. This imperfect action may arise from many causes, such as excess of albumen at the part, the surface

having been touched with greasy fingers; or from air bubbles forming between the prints immersed. In your case it is probable that this is the cause, as you state that the dish is just the size of the print. The fact that you keep the dish moving in such a case, is not of much use; the prints should be moved, and it is a good plan to keep turning them over. If a spot of imperfect toning is observed to be forming, from a greasy mark on the albumen, the print may be removed and immersed in a 10-grain solution of carbonate of soda for a few minutes, then thoroughly washed and returned to the toning bath, and all will probably go well. If an air bubble have been the cause, sometimes a little friction with the finger on the untuned part will increase the action of the solution at that point, and enable it to overtake the rest. The red spots in printing were most likely from some imperfection in the paper; but there can be no reason for increased tendency to the spots in large pictures more than in small ones, except, of course, the greater area presenting more chances for defect.

D. C.—You can adopt two methods to obtain paper prints from glass positives. You may copy them, and produce printing negatives; or, if they have been sufficiently well exposed, you may convert them into negatives; but in that there is always a slight degree of risk. However, proceed as follows:—Remove the black varnish by friction and turpentine; then, if the white varnish have been what is termed "crystal varnish," remove it by repeated washing with benzole or chloroform; moisten the film, and apply a solution of iodine 1 grain, iodide of potassium 2 grains, water 1 ounce; wash off, and intensify with pyro and silver. If it be a spirit varnish, first moisten with alcohol, and then apply an alcoholic solution of iodine, about 5 grains to the ounce, for a few minutes; wash off with alcohol, and intensify with an alcoholic solution of pyrogallie acid, containing a few drops of an alcoholic solution of nitrate of silver.

AMATEUR T. L. P.—The stains you describe as occurring at the bottom of your plate most probably arise from the drainings of the plate coming into contact with the wood of the inner frame. Use a piece of clean blotting paper at the bottom of each plate to collect the drainings. 2. The toning bath should be as nearly as possible neutral. The bath turning purple shows that it is decomposed, and has precipitated the gold. This is caused by the addition of carbonate of soda, which should never be used for a bath intended to keep.

W. CASEY.—The spots have been caused either by a trace of hyposulphite of soda touching the print before it was fixed, or from a trace of nitrate of silver touching it before all the hypo was removed. It is a stain of decomposed hyposulphite of silver.

P. C. J.—You have still a flat effect, apparently from a light too equally diffused all round the sitter. The pictures appear as if you placed the sitter facing the light, thus making your light a front light, the worst you could use. The vignetting will not do; both figure and background must graduate into white much more imperceptibly. The plan is to cut an aperture in a piece of card of an irregular oval shape. Round the edges of this, gun cotton-wool, and, with your fingers and a pin, pull its edges out so as to graduate the light passing through the fringed edges. This mask may then be laid outside the pressure frame, and, by a little care, will give excellent vignettes.

W. W. S.—A decided improvement. No. 2 is very good indeed. No. 1 is a little hard, and No. 3 a little flat in the face; but all are improvements. The tones are pretty good, but might be richer.

DOUNT.—Corrugated iron answers well, we believe, for the opaque parts of glass houses; how far it will answer for the sashes, we cannot say. Iron has one disadvantage, that it presents us little facility for fastening curtains, drapery, &c., inside. We believe the iron roof answers, but we have no certain means of knowing.

SCOR.—Theoretically, it is better to focus with the aperture you are going to use, as, with some lenses, the focus is thrown a little back when a small stop is put in. But if the stop make it too dark to focus conveniently, use an aperture sufficiently large for convenience in focussing, and then change. With a good lens very little difference is made in the position of the focus by the stop.

J. GILBERT.—Mr. Williams has given up publishing stereoscopic slides for many years. We think it is probable that the last stereos of Warwick Castle and neighbourhood are by Mr. Bedford, published by Messrs. Catherall and Pritchard, Chester. We cannot tell you how many sheets of paper 20 ounces of albumen will coat. The albumen, of course, gets gradually thicker from evaporation, and each sheet will vary very slightly. The keeping qualities of albumen vary with temperature and other circumstances. Nothing is better than pure albumen for giving a good surface. Float the paper, and remove as quickly as possible. We believe albumenizing twice will give a higher surface, but increases danger of streaks.

DELL PHOTOGRAPHY.—When you add acetic acid to an alkaline bath, you form acetate of silver, and this is frequently a source of streaks, spots, &c. You should have commenced by adding the carbonate of soda, then sunning and filtering, and finally adding a trace of nitric acid. It is now a difficult matter to get rid of the acetate of silver.

J. A. B.—Where the blisters disappear on drying, we do not think that any danger to the print need be apprehended. It is, however, important to wash well, so that no trace of the hypo may be retained in the vesicles formed by the blisters.

A. BROTHERS.—No photograph has arrived by post, or otherwise.
MERLIN—Shall be considered. You had better give us a Post-office address. Several letters and articles are compelled to stand over.
Several Correspondents in our next.

A RAPID DRY PROCESS.

WE have recently had an opportunity of trying some dry plates of extraordinary sensitiveness and general excellence. We have tried two entirely different samples, by different processes and different persons, and both possess unusually good qualities. One lot was prepared by Mr. Bartholomew by a process which we give below; the other by Mr. Hurst, of Mirfield, prepared by a process which we hope to publish, shortly. The latter gentleman called upon us a few weeks ago, and favoured us with a sight of some exquisitely fine stereo negatives, all taken with very rapid exposures, some possessing good clouds. He left a few of his prepared plates for our own testing, and promised, when he had quite satisfied himself as to the very best conditions, to give us further details.

About the same time we received a note from our correspondent, Mr. Bartholomew, which excited our interest. It ran as follows:—

I have been using some dry plates of great sensitiveness lately, and I am sure they completely overthrow Mr. Sutton's froe nitrate principle, for they are thoroughly and completely washed, and require about ten seconds' exposure for an open sunlit view, at 10 A.M. this month, Dallmeyer's No. 1 triple lens, stop No. 2. If you can find any spare time to try a few $4\frac{1}{2} \times 3\frac{1}{2}$, may I send some? *I guarantee success!* Cold pyrogallie development, and no bother about a moveable film (under reasonable treatment). Many of the recent tannin modifications are very good, but here is a formula far easier of preparation, far more sensitive, and, I think, producing unsurpassed negatives.

We subsequently received two or three other communications from Mr. Bartholomew, all of them speaking of confirmatory evidence as to the rapidity and excellence of the process, and explaining that it was simply a modification of the alkaline process he had proposed nearly two years ago. We prefer to state the matter in his own words, and subjoin, therefore, the following letter:—

DEAR SIR,—Your correspondent, "Delta," calls attention to my alkaline-gelatine process, as involving the principle of alkaline development, which it certainly does, if plain pyro and water is used to commence development. Curiously enough, his remarks have appeared just at the time when I have completed some trials of dry plates prepared by a plan I have long proposed to myself, but hitherto forborne carrying out; in fact, I have shelved this alkaline process, and devoted more attention to the simply washed and dried film formula until now: the present time, then, appears to me rather apropos to say a few words on the matter. Well, these plates are with me the most sensitive dry films I have prepared, and stains, &c., are not present, I may say, in more than their fair proportion, being nearly absent altogether.

I am afraid to speak of the exposure required, but will give a faithful *resumé* of the time of one plate as a guide; ten days ago (about), $9\frac{3}{4}$ A.M., $7\frac{1}{2} \times 5$ plate, No. 1 triple lens, No. 2 stop, sunlit view of church, 15 seconds, cold pyro and water development, followed by the usual silver and acid addition to intensify; this negative was visible directly on the application of the

pyro and water, and was completed in intensity in less than five minutes; sky printing through, and foreground corners vigorously brought out, thus evidently verging on over-exposure.

I hope any prejudice existing to part of the formula may be laid aside, and a fair trial be made of it; after the manner of Mr. Sutton, allow me to recommend a trial of *my* process, which is to coat and sensitize a plate in my morphine bath, wash as in the tannin process, drain a little, and coat with a solution of—

Gelatine	5 or more grains
Water... ..	1 ounce
Bicarbonate soda	$0\frac{1}{2}$ grain

dissolved by heat and filter, then apply hot to the plate; wipe the back and place to dry evenly, as usual; develop with pyro and water, and intensify with pyro, acid, and silver, as usual.

I do not state positively a morphine bath is indispensable, not having compared results, except from memory; but I am led to believe that the sensitiveness *is* greater from these new trials.—Yours faithfully,

WM. BARTHOLOMEW.

Egham, October 5th 1863.

We received from Mr. Bartholomew a box of plates, which, on the first convenient occasion, we exposed and developed. How long they had been prepared we cannot tell; but they had been in our possession nine days. The light was unfortunately very poor, without direct sunlight, and a somewhat hazy atmosphere. We used a Dallmeyer's No. 1 B lens, with various stops, and for the first exposure gave about double the time we should have judged necessary for a good wet plate with iron development. The plate was a little over-exposed. Sundry other exposures eventually decided us that about one-half longer than for wet collodion gave us the best results. With the lens in question, of about six inches focus, and a stop of half an inch, we got a good negative with an exposure of fifteen seconds, in a dull, diffused light, the subject a portrait and foliage.

In development we proceeded as follows:—Having first moistened the film with common New River water, we then applied a three-grain solution of pyrogallie acid, with acid of silver: very rapidly an image appeared, distinct and red by reflected light, but feeble and phantom-like when examined by transmitted light. In the course of about a minute, all the detail being well out, we added a few drops of a solution, containing ten grains of citric acid and ten grains of nitrate of silver to an ounce of water. The required intensity was now easily and quickly attained; the whole process of development occupying little more time than would have been required for a wet plate. The deposit was of an extremely non-actinic colour, resembling a collodio-albumen plate, with the general tint by reflected light of a good pyrogallie acid negative. In some cases where the plates were not handled with sufficient care, there was a slight tendency to loosening and wrinkling of the film; but, with care, this was avoided, and there was no danger in any case of losing a film. Altogether, our experiments with the plates were decidedly satisfactory.

Mr. Bartholomew, in a subsequent letter, states that the collodion he uses contains a full proportion of a bromide, but does not state how much. He states his conviction, also, that a little sugar or honey added to the gelatine solution would probably both add to the sensitiveness of the plates, and prevent any tendency to wrinkling and loosening of the film.

Mr. Hurst's plates are produced by a modification of the tannin process, the nature of which we do not know. They present several features quite distinct from those of Mr. Bartholomew. The latter, when wet, are more transparent than when dry. Those of Mr. Hurst, when moistened, become more opaque and creamy; and in this respect resemble those of Dr. Hill Norris. They are scarcely quite so sensitive in our hands as those we have noticed above; but they were extremely rapid, and behaved exceedingly well in development. They appeared to require an exposure of about twice that of ordinary wet collodion. They received the same treatment in development as the others, and rapidly gave clean, bright, satisfactory negatives, without the slightest tendency to losing or moving. With a pair of Dallmeyer's stereo lenses, and a stop of three-eighths of an inch an exposure of forty seconds gave us a good negative in a dull light. Some of Mr. Hurst's quasi-instantaneous exposures in a good light gave good negatives. We shall look with much interest for further information regarding them.

Before quitting the subject, we have another reclamation to make on behalf of Mr. Bartholomew. In the last number of the *Photographic Notes*, Mr. Sutton refers to a "new rapid dry process, the discovery of the well-known amateur Mr. Thomas Fothergill," which yielded, in the hands of a gentleman in Jersey, results equal in rapidity and quality to wet collodion. Mr. Fothergill's letter referring to the subject, does not, however, claim any discovery, but states that he has "adopted the valuable suggestion made by Mr. Hannaford, two years since, of pouring the albuminate of silver over the plate instead of relying on the production of that substance in the body of the collodion as formerly," referring to the plan adopted in the old Fothergill process. The method now adopted was first suggested by Mr. Bartholomew, in February, 1861, in a letter in our pages; and we received from him a negative by the process. We then expressed a doubt on the keeping qualities, as Mr. Sutton now does. Mr. Hannaford, a few months afterwards, quite independently, we believe, having overlooked the letter in question, made a similar suggestion at the South London Photographic Society. We at that time accredited Mr. Bartholomew with the original suggestion; and now, whilst we esteem the labours of Mr. Hannaford very highly, and have considerable regard for him as a personal friend, we feel it to be simple justice to Mr. Bartholomew that his priority should be acknowledged.

THE PHOTOGRAPHIC EXCHANGE CLUB.

The Exchange Club, established nearly five years ago by the conductors of this journal, under the title of the Stereo Exchange Club, and subsequently, under modified conditions, as the Photographic Exchange Club, has, during that time, been carried on with varying success and satisfaction. The system of exchange, originally proposed and carried out, was on this wise:—Photographers wishing to possess the stereoscopic pictures of others in exchange for their own, were invited to forward specimens of their work to the Editor of this journal for his approval as fair materials for exchange. At convenient intervals, a list of the names and addresses of those whose productions were considered satisfactory was published in our columns, and members then exchanged with each other, either with or without correspondence. It was customary to send one experimental print to each gentleman whose name was published, in order to ascertain the quality of the returns which might be expected, and then the exchanges were extended further between those

whose productions pleased each other. This system worked very well for a time; but complaints every now and then reached us of very inferior returns being sent for good prints.

This led eventually to a change. It was agreed that a secretary should be appointed, who, assisted by a couple of referees, should conduct the exchanges. All prints were to be forwarded to Mr. Howard, who volunteered to undertake the somewhat onerous duties of Secretary, and it was arranged that his judgment, and that of the referees, were to be the final standard of appeal in deciding the relative worth of the pictures, stereoscopic and others, sent for exchange. An equitable apportionment was to be made; and where prints absolutely worthless were sent in, they were to be returned to the sender. For a time this promised well; but has gradually, from a variety of causes, all of which we cannot even guess, becoming less satisfactory in its operation. A large number of very poor prints have been sent in, and frequently such as were absolutely worthless. Thus the Secretary's honorary duties have become irksome, and without sufficient satisfaction in the result to others to induce him longer to continue them. Mr. Howard has, therefore, resigned the office of Secretary, which, for two years, he has so well filled. We regret the issue, and we regret its cause. We can only express our own sense of the indebtedness of every member of the Club to him for the ungrudging expenditure of time, labour, and money in their behalf, for it was impossible to fill such an office without being occasionally out of pocket, as well as heavily taxed in time. We append the letter we have received announcing his intention:

DEAR SIR,—I have to inform you of my intention to relinquish the position of Secretary to the Photographic Exchange Club. The difficulty of successfully managing the exchanges so as to avoid the invidious position in which I feel myself, together with the lack of support, alluded to in my last letter, has induced me to take this step, which I shall feel obliged if you will announce in the NEWS.

I would suggest that the Club be started afresh, as before October, 1861, viz., by gentlemen forwarding their names and addresses to you, simply adding to the old rules the privilege of declining a proffered exchange, should a member be dissatisfied with the sample sent.—I am, dear sir, yours truly,

F. HOWARD.

10, Lansdowne Road North, South Lambeth,
October 16th, 1863.

We have also received several letters from members of the Club regretting the probable termination of the exchange system, and making suggestions. We select a couple for publication:—

DEAR SIR,—I have been for some time a member of the Photographic Exchange Club, and am highly satisfied with the manner in which Mr. Howard, the Secretary, and the Committee have performed their duties; and, therefore, it is with great regret that I received a letter from Mr. Howard this morning, in which he stated "that he had determined to relinquish the office of Secretary." After having read the letter from him that you published a few weeks ago, I cannot wonder at the decision that he has come to, as it must be very discouraging to a lover of the art to see the standard deteriorating instead of improving steadily, as it ought to do. I have no doubt this arises, not from the original members becoming less expert, but from many of them ceasing to contribute, and their places being filled by others who are probably beginners in the art.

I should be very sorry, indeed, if the Club should entirely pass out of existence, as, by its means, hundreds of beautiful pictures have been distributed, which might probably otherwise never have been seen by any photographers but those who produced them. I therefore appeal to you, and through you to photographers who take an interest in something besides portraiture, to make some effort to continue the working of the Club.

I will not suggest the appointment of new officers, as I believe the failure of the Club is not in the slightest degree owing to any omission or fault on the part of the present Secretary or Committee; but rather owing to a slackening in the zeal of the members, which may partially have been caused by

the Club having been carried on through the summer months, when many, especially professional photographers, have their time too fully occupied to make exchanges. I would, therefore, suggest that in futuro it shall be discontinued during the *summer months* (say from April to September), in order that it may commence with fresh vigour after lying dormant for a while.

If you, or any of your influential readers, cannot organize any new scheme likely to succeed, let us go back to the old system as it was before 1861, and take our chance of receiving bad exchanges rather than have none at all. I shall be glad to co-operate in any scheme you may suggest for the continuance of the Club.

I have sent you a few of my stereos by book post, and shall be glad to hear your opinion of them.—I remain, yours respectfully,

J. P. GIBSON.

Hexham, October 17, 1863.

SIR,—I regret to find that Mr. Howard is obliged to relinquish the office of Secretary to the Exchange Club, as it is perfectly clear that under those circumstances the Club (to use an Americanism) will go under and be wiped out. Surely, the members of the Club will make an effort to avert this ending of what must have been a source of some pleasure to all who have sent prints for exchange, and even those unfortunates, whose prints were sent back, must admit that Mr. Howard's courtesy and kindness softened the disappointment, and encouraged them to try again and do better next time.

I cannot but think that the members of the Club only require to know the fact that it depends solely upon themselves whether the Club lives or dies, to make them come forward now, as they did when it was commenced, and revive it.

I think it such a pity that it should fall to pieces when it was working so well as it has been doing. It cannot be that all the members have used up all their negatives, there must be some that have not been exchanged: if they would only set to work and take advantage of the first fine day to print off a batch, I hope Mr. Howard would be persuaded to resume his office.

I agree with what you said, a week or so back, that it enhances the pleasure of taking a fine view much, to know that you will be able to obtain others, in exchange, of places you may never be able to visit.

Apologizing for so long a letter, I remain, Sir, yours, &c.,

ONE OF THE CLUB.

London, Oct. 17th, 1863.

For our own part, we shall readily give effect, so far as we can, to any decision at which the members may arrive. It is possible that a recurrence to the old system, without confining its operations to stereographs, may be found most satisfactory. We leave the subject in the hands of those concerned, without further comment at present, merely inviting those who have plans to suggest to communicate them for consideration.

A COSTLY LENS.

WE have just received a letter from Mr. J. W. Osborne, who is in Berlin, carrying out, in conjunction with one of the first European lithographers, some important experiments and works in photolithography, some further particulars in regard to which we hope to publish shortly. Amongst other interesting photographic items, he informs us that he has just secured from the Melbourne Government instructions to order from Mr. Dallmeyer, to be used in the copying of maps to be photolithographed, a lens which shall cost £250. As this is an unprecedentedly large sum for a photographic lens, a short history of the matter may be interesting to our readers.

Some two or three years ago, Mr. Hardwich received from Mr. Osborne, the Photographer to the Melbourne Government, a letter, asking him to undertake an examination of some of the new lenses recently introduced to photographers, with a view to sending him one of the most perfect. The issue was, the purchase of a No. 6 Triple Achromatic, which was accordingly sent, and has given the fullest satisfaction. But Mr. Osborne, whose keen judgment and enterprising

spirit is ever looking to a higher perfection, conceived the idea of a lens ground on principles which had not hitherto been attempted for photographic purposes on account of its costliness and unnecessary refinement for ordinary use. It may be necessary here to make a brief explanation. In the polishing of photographic lenses, as in many other matters, a compromise is accepted in place of the highest theoretical perfection. The surface of the lens, which looks so smooth and bright to the eye, is really not a perfect continuous surface, without the slightest inequality. If carefully examined with a powerful glass, or by reflection, it is seen that the small hills and hollows (remains of the last stages of the grinding process) still exist, although sufficiently polished over to give it to the naked eye the appearance of a fine and continuous surface. In the common cheap lenses this surface is often very imperfect indeed; whilst in the lenses of the best makers the most perfect surface to be obtained by the means available is secured; and the difference in result between this and that of the common lenses is often apparent to the naked eye. For most photographic purposes the result thus obtained by good makers is all-sufficient. There is, however, a method of obtaining a still more perfect surface, but at a great cost of means and labour. The method in question is used for grinding and polishing the object glasses of the best larger telescopes, in which the high magnifying power employed renders apparent the most insignificant imperfection of the surface. In these lenses the time required for each surface is always weeks, so that a triple lens so ground and polished, having twelve surfaces, would probably require months to complete the glasses, during the whole of which time machinery would require to be kept in action, and the continued close attention of the most skilled optician directed to watching and governing the result. By this method a perfectly equal continuous spherical surface is obtained, and with the highest possible polish.

For ordinary photographic purposes, such a lens would be as unnecessary as it would be necessarily costly; indeed, we do not imagine that anything would be gained by it. But Mr. Osborne conceives that for copying maps, &c., for photolithography in which the most perfect delineation of the finest lines becomes a matter most vital to the highest success, the value of such a lens becomes a consideration of no light import. He accordingly laid the question fully before his Department with all the arguments belonging to the case. The issue is, that he has received an official communication from Mr. Ligar, the Surveyor-General, informing him that the matter had been duly considered by the Minister, that it had received approval, and he was instructed to place the matter at once in the hands of Mr. Dallmeyer, with whom he (Mr. Osborne) had fully discussed the matter when he was in England.

"The most perfect definition," Mr. Osborne writes, "is, I conceive, a fundamental condition necessary for photolithographic work, for without this it is impossible to compete with the draftsmen on stone, and that definition I hope to get with a lens, ground and polished, and the astronomical method." After asking our personal aid in occasional superintendence of the matter during his absence on the continent, Mr. Osborne adds: "I have great faith in Dallmeyer, and I am sure he will exert himself to the utmost; and, as far as form is concerned, I leave the matter entirely in his hands. The experiment is altogether an exceptional one, but I hold that such exceptional experiments should be tried by public departments; and, in the present case, I think some credit is due to the Melbourne Survey Office, and its head, Mr. Ligar, for showing the way in this matter."

We cordially agree with Mr. Osborne in this view of the case. And as part of the heavy cost will arise from the necessity of constructing new tools for the especial case, if the experiment should prove as great a success as it ought, the photographic public will gain, not merely in the demonstration of an important fact, but in the modified future price, rendered possible by the present liberality and enterprise of the Melbourne Government.

Scientific Gossip.

PHOTOMETRIC VALUE OF THE ELECTRIC LIGHT—THE CHEMISTRY OF PAINTING—DISCOVERY OF ROCK SALT.

THE electric light has often been referred to in these pages, and photographers must be well aware that it is the most powerful source of artificial light which we possess, and also the one richest in chemical rays, exceeding in this respect the sun itself. Some doubt has hitherto prevailed respecting the relative intensity of the electric, as compared with ordinary light, owing doubtless, partly to the difficulty experienced in measuring photometrically so brilliant an evolution, and partly, perhaps, to the expensive character of the light, and the consequent somewhat rarity of its production. The only accurate experiment which we can recall at this moment, is by Bunsen, which was made with a battery of forty-eight carbon cells, in which he estimated the photometric equivalent of the light at 572 candles. An opportunity has been recently afforded for Professor W. B. Rogers to make some accurate experiments on this subject, in which the battery consisted of 250 carbon elements, each having an active zinc surface of 85 square inches. These were grouped in five battalions of 50 each, and the light was arranged in an apartment where a range of about fifty feet could be obtained for the photometric apparatus. Instead of an ordinary standard light equivalent to twenty candles, a unit was substituted ten times as great, equivalent therefore to 200 candles.

The photometer was the one known, we believe, as Bunsen's. It consists essentially of two pieces of paper, a circular disc in the centre of each having been touched with oil to increase the transparency. They are placed close together, facing the observer, and reflectors are so arranged at their back that the standard light illuminated one whilst the electric light illuminated the other. The pieces of paper are enclosed at the other end of a dark box, in the front of which is an aperture for the observer's face, a cloth or similar contrivance being placed to keep out all extraneous light. The observer, therefore, sees at a convenient distance in front of him two illuminated discs of paper. By altering the distance between one of the lights and the photometer, the amount of luminosity of either disc can be regulated at will, and owing to the law of the diminution of light in the inverse ratio of the square of its distance from the source, it is not difficult to so adjust the distances, that the discs of paper shall be equally illuminated. This having been effected, it is a matter of simple calculation, to obtain the relative photometric values of the two sources of illumination.

In this experiment, the photometer and standard lamp were fastened at a fixed distance apart, and were arranged to slide on a horizontal graduated bar, extending towards the carbon points of the electric light, and the platform was moved to and fro, until the illumination of the discs was equal. It was found by a series of experiments that the electric light was equivalent to from 52 to 51 times that of the standard light, making it as intense in illuminating power as 10,000 to 12,000 standard sperm candles. This degree of intensity, it must be remembered, is that of the naked light, unaided by a reflector; when the rays are concentrated by a parabolic reflector, the power is enormously increased, its illuminating force being then equivalent to several millions of candles, all pouring forth their light at the same time. Comparing the luminous power with the number of battery cells, it will be seen that in Bunsen's estimate the proportion was nearly twelve candles to the cell, whilst Professor Rogers' estimate is about forty candles to the cell. This difference is no doubt due to the greater intensity of the battery, and the cumulative effect of its arrangement.

Mr. Holman Hunt has suggested to the Royal Academy commission, that there should be a professor of chemistry appointed by that body, who should devote his time to the study and explanation of the properties of colours,

how they affect each other when mixed, what are the values, as regards permanency, &c., of the different new pigments which are so constantly being brought forward, and what new pigments may be safely introduced. The suggestion is one that we would earnestly press on the attention of the commission, as it would tend materially to the advancement of art. Chemistry is constantly giving new and beautiful colours to the artist, and it is capable of informing him of their degree of permanency when exposed either to the chemical action of the atmosphere and its gaseous impurities, or to the fading effect of long exposure to light. This information, indeed, is generally given with every new colour, the introducers being in most cases alive to the advantage of having their own laudations backed by a competent scientific authority; but there is another branch of chemistry in relation to art which is not so frequently studied, owing to the fact that it is no person's particular business to do so, and that is the mutual action of pigments one on the other, and the influence on them of the vehicles in which they are employed. It is a notorious fact that modern paintings do not stand. Those who will notice the paintings in the galleries at South Kensington, and remember what they were some years ago, cannot fail to be struck with the alterations which a few years have made in some of our best pictures. These changes must not be fairly ascribed to the injurious action of light, or the deleterious gases present in the atmosphere, they are more probably the results of the action of pigment upon pigment and of alteration in the vehicles and varnishes employed, and these being mixed with no regard whatever to the chemistry of the various materials it is a wonder that some of them stand as well as they do. The only object of the artist in preparing his palette is to get the required shade in a mixture that will work easily. The old masters, who had none of the modern resources of test tube and precipitating glass, were obliged to content themselves with such mineral colours as were given them by nature: these were consequently of great stability, and were ground in the simplest possible media. Their productions have for the most part stood unaltered, except as regards the mellowing of tone by the darkening of the varnishes employed; but will anyone venture to predict that modern paintings will be equally permanent? The fact is, that brilliancy of colour is principally aimed at, and permanency is lost sight of, except by some few exceptional artists. The preparation of pigments has gradually been withdrawn from the artist's studio to the chemist's laboratory, and as it is not likely that every artist would care about undergoing a course of chemistry as a preparatory initiation into the mysteries of his art, it is a necessity that there should be a properly authorized professor of chemistry whose duty it should be to examine every new claimant for the honours of the palette, and not to admit the colour, however brilliant, unless it has proved to possess the more sterling qualities of stability and innocuousness. We sincerely hope the Academy will adopt Mr. Hunt's suggestion, and elect a Professor of Chemistry, who shall found an art standing in the same relation to painting that pharmacy does to medicine.

Common salt is not so expensive a commodity that a new source is of much importance to photographers; nevertheless, our readers will feel interested in learning that an extensive deposit of rock salt has been discovered at Middlesbro'-on-Tees, under the new red sandstone. It lies about 200 fathoms deep, and has a thickness of about 120 feet. The district is full of chemical works, where common salt is one of their staple articles of consumption, being used as the source of soda. This discovery will, therefore, prove very valuable to this part of England, as it will entirely take the salt trade from Liverpool and the Nantwich mines. Its extent laterally has, of course, not been ascertained; but there is no doubt that it is very extensive, for it is now pretty well understood that rock salt lies in large natural basins, as if the water of a salt lake or sea arm had been evaporated, and the salt left behind.

A DOZEN BRIEF HINTS TO PORTRAITISTS.

I CHANCED to be in a photographic establishment, not many days since, when there came in a portly, well-dressed man, who, in a bustling, business-like way, enquired if any back grounds were wanted? Receiving encouragement, he brought in from his chaise, at the door, a roll of "slips" and a roll of backgrounds, and proceeded to display them, one after the other, with many eulogistic remarks on their respective merits and beauties. The proprietor purchased two of the "slips," and when the vendor had departed, inquired of me if they were not "first-rate," to which question I evaded giving a direct reply.

Now, the price at which these were sold set me a-thinking. I guessed, from the appearance of the vendor, that he must secure the lion's share of the profit upon such goods, but I knew that even this share must render a very brisk trade necessary to make such sales as he effected sufficiently remunerative. Putting down his share, then, at the lowest possible figure in connection with what I considered the brisk trade aforesaid, and adding to this the cost of material procured in the cheapest market, I found that the unfortunate painters of such slips and backgrounds must be labouring very hard to earn enough to provide each one person with the commonest necessaries of life, in life's most poverty-stricken aspect.

From the vendor and producers my thoughts turned to the purchaser. He was a photographer holding a respectable position in his profession, and ambitious, to use his own words, of "turning out nothing not first-rate." His glass-room was fitted up with all the best approved appliances, his operator was a very skilful, well-paid gentleman, he carefully overlooked every print sent out from his establishment, and his lenses were chosen, not for their cheapness, but for their excellence.

These lenses brought me to the point I wish here to briefly dwell upon. The grand virtue of a good lens is to render natural objects on the sensitized plate with the truth they possess when thrown upon the retina of the eye. a lens which distorts or gives unfaithful images being speedily rejected by any gentleman who wishes his pictures to be *in good drawing*, as an artist would say.

And yet here was a gentleman anxious to produce, or "turn out nothing not first-rate," and increasing the expenses of conducting his business very materially in carrying out such a view, purchasing, for introduction into his pictures, such ludicrous specimens of distortion and unfaithfulness, or, in other words, bad drawing, as the very worst lens of the very worst maker could not possibly equal.

Then comes the thought what a great number of photographers there must be acting in this singularly inconsistent way if these vendors of cheap backgrounds, slips, &c., can succeed in making their business at all a paying one: and I am assured, on the very best of authority, that such itinerant dealers abound all over the country, as well as in London, and really drive a very brisk and profitable trade.

Under these circumstances I thought a few hints to portraitists on the subject of backgrounds would not, just now, come amiss.

1st. Pictorial backgrounds should be drawn in correct perspective according to the position of the lens in regard to the sitter, or model.

2nd. It should be so managed as to give an effect of space behind the sitter, in order to relieve and throw forward the head and figure, and render the portrait the most prominent thing in the picture.

3rd. It should contain neither white nor black, nor anything approximating thereto, because, while white would destroy the prominence of the lighter portions of the head by coming forward with the same degree of power; black would destroy the force of the shadows in the head and figure, and so tend to weaken the effect of relief.

4th. It should be so contrived as to have its darker portions on that side against which the lighted side of the face

comes, and its lighter portions on that side which relieves the shadowed side, because the contrast thus obtained gives brilliancy to the lights and force to the shadows in a manner far more legitimate and effective than that of slightly under-exposing, and so losing half-tints in the shadows, or that of seeking the extreme of brilliancy by chemical and manipulative means.

5th. In a landscape background a little violation of truth is *perhaps* permissible; we have, at any rate, precedent for it in the best works of our greatest portrait painters. As an instance, I will mention the low position usually assigned to the horizontal line or line of the horizon. As most people know, the height of this line indicates the height of the spectator's eyes, and consequently regulates the general effect of every object in the picture. If you place yourself before a window commanding a view of the horizon, you may readily convince yourself of this, supposing you to be ignorant of the fact. Sit or kneel and mark on the glass the height of the horizon. Then rise, and the horizon rises with you, still retaining the level of your eyes. In the case of a photograph, of course, the spectator is represented by the camera and the height of the horizon, to which every line converging from the said spectator ascends or descends, is, or should, to be strictly correct, be the same as that of the camera. But the air of majesty and consequence given to a figure when the line of the horizon is kept low, is supposed to justify a violation of truth in this respect. As to the legitimacy and propriety of such a plan, and when or under what circumstances it is to be used, therein must a man be his own judge. I need only say that the ablest and greatest masters in art have not hesitated to adopt it when their subject seemed to require such treatment.

6th. In an interior, consisting, as it largely does, of lines, care should be taken to compose these lines well with the figure. You must remember that a point catches the eye without retaining its glance, while a line carries the eye along its whole length, and if these lines are so artfully designed as to carry the glance of the spectator, wherever it may chance to fall, back from every quarter to the prominent or most important object in your picture, viz., the head, these lines then do their duty. They have, at any rate, no right to take the eye *out* of the picture.

7th. When you use your background, placed at some distance from the sitter, or take your picture with a short focussed lens, have the lines in it painted much finer, and rather stronger than would otherwise be necessary, and for this reason: lines out of focus are thickened and weakened. The same rule applies to the general effect to be got in backgrounds thus used; that is to say, allowance should be made for the blurring, thickening, and weakening of every touch applied in the painting thereof.

8th. Let the painter of your background see a picture taken in your glass room, and fairly representative of your work, so that he may adapt the character of his work to the character of your work. If you use a thin negative, having but little intensity, the contrasts of light and shade in the background may be tolerably powerful; but if you use an intense negative there cannot be too little contrast in the painted background. I have seen a background used by two different operators assume two strikingly contrasting appearances. In the thin negative it was perfect—soft, quiet, harmonious, and subordinate; while in the intense negative it was hard, staring, and presumptuous. The same process that had destroyed the delicate half-tints of the face, and converted them into staring patches of white paper, having also taken out the more tender tints of the landscape, and put bold white in the place of modest grey.

9th. Have your backgrounds painted in black and white, rather than in colours or browns. The argument against colours in backgrounds needs no urging, being generally understood. And yet blue skies, and violet castles, and green trees are still to be seen in these productions, one manufacturer, who boasts a large business, invariably using colours, because, as he says, they "look prettier, and sell better." The

use of brown certainly gives a less sombre and gloomy effect to the background, when in the glass studio, and has a nice, warm, cheerful effect, but argument against their use is here in a nutshell. The brown is warm, or, in other words, contains red, and so, where the colour is used thin, and where the colour is used thick, presents not only a contrast of light and dark visible to the eye, but a contrast of chemical action only visible in their action on the sensitized plate.

10th. When you use a landscape background, adopt the plan first introduced, I believe, by Mr. Wall, some years ago, viz., that of having the lower part of the background long enough to be stretched upon the floor of the room, and painted in imitation of earth, &c., so as to blend with, and seem part of, the background itself. Some very excellent effects have been got in this way far surpassing that of a piece of plain floor-cloth, or the sweeping of a quantity of gravel and straw about the feet of the model.

11th. Is, oh! most heterodox! for it says, avoid those scrupulously clean, neat, smooth, spotlessly flat backgrounds, which are so destructive of relief, and space, and breadth, and artistic effect, which give the figure an appearance of being inlaid, and have been avoided in all real works of art ever since the middle ages. A graduated background, or a background having its own lights and shades, and indicative of some amount of atmosphere or distance between it and the portraits, is the right and proper thing, not a clean newly-painted wall one or two feet from the head.

12th. If you desire the background to look real, and as if taken at the same time with the figure from nature, it must not only be well and skilfully painted, but the point of sight, or, strictly speaking, the vanishing point, to which all the high and low lines converge, should be exactly opposite the point of view represented in the position occupied by your camera. The light on the figure and the light on the background must also be the same. So ends my dozen hints on backgrounds. R. A. S.

JOTTINGS FROM THE NOTE-BOOK OF A "PHOTOGRAPHER'S ASSISTANT."

No. IV.

THEORY OF THE ACTION OF LIGHT.—TIME OF EXPOSURE.

DURING the summer of 1862, a suggestion thrown out by Mr. George Price, in one of his ably-written papers, induced us to undertake a series of experiments in order to trace out the agents employed in the production of the image on the surface of albumenized paper. From the results of these experiments (which in a future jotting will be given in detail) we were drawn almost against our will to the conclusion that during the process of sensitizing, although the silver enters freely into combination with the albumen, the union between the metal and the chloride salts is not to any perceptible extent determined until exposure to the electric influence of the actinic rays. We are aware this newly-pounded doctrine will be regarded by many as a photographic heresy, but let it be remembered that the chloride salts, as associated with dried albumen, exist in a crystalline form, and no union can be effected with the silver, under the conditions present in sensitizing operations, until the above-named salts have yielded to the solvent action of the liquid. In plain salted papers this power is easily brought to bear on the substance named, because the unguarded interstices offer no obstruction to the admission of the fluid; but with an albumen surface the conditions alter, and the solvent agent is unable to act upon a tithe of the salts incorporated with the albumen. A minute portion of the chloride of silver is, we admit, formed on the immediate surface of the albumen during the time of floating, but the quantity is so small that its presence cannot be detected when the paper is submitted to a thorough washing in distilled water, previous to exposure to light; although, under the conditions described, the albuminate remains as sensitive

as a surface of the same substance, prepared free from chlorides, and exposed to light without washing. Now, if in the first-named experiment chloride of silver was present, its modifying influence in colour and sensitiveness would immediately lead to its detection; but if, on the other hand, the salt was dissolved out during the process of washing, it being an insoluble salt, its separated existence would speedily be proved.

It is generally admitted that the albuminate of silver forms the staple part of the picture, as, doubtless, it does so, because its production is unobstructed by accidental causes; but, at the same time, without the pressure of a more sensitive agent, printing operations would be a tedious and altogether unsatisfactory affair. We have now to inquire how the union between the silver and the chloride salt is effected, if not so during the process of sensitizing. Every person who has had anything like experience in photographic printing must have observed the additional vigour and sensitiveness gained by the presence of a small amount of moisture in his paper. It must be admitted this dampness would assist materially any process of decomposition that may be going on; and as moisture is a good electric conductor, we believe the union is effected by the decomposing agency of the last-named power, whose action is set up directly the paper is exposed to the light, and by this action the chlorine is separated from its base, its strong affinity for silver causes it to seize upon the free nitrate, and a second decomposition ensues; hence the necessity for a portion of the last-named salt remaining in a free condition on the surface of the paper. To prove that a union such as we have described is brought about by the agency of actinism, is possible: it is only necessary to place into close contact a portion of nitrate of silver with one of the chloride salts, on exposure to light decomposition such as we have described immediately commences.

An objection may here be urged, which, at first sight, would appear reasonable, viz.: If the combination between the chlorine and metal is effected by light, how is it to be explained, that the stronger the power exercised by the sun's rays the redder the picture produced, when it is well known that a chloride of silver is changed by that agent to a violet hue?

We have before alluded to the comparatively insensitive nature of silver in combination with albumen, consequently, a weak light will show the presence of the more sensitive chloride of the metal better than a strong one, because, under the influence of the last-named conditions, a larger portion of the organic compound is reduced, and its characteristic brickdust colour overpowers the modest violet hue the chloride produces, for the following reason:—"Among the molecules that reflect colours of a single order, those which furnish red are the thickest, and those that give violet are the thinnest." Hence it will be perceived, that the greater the reduction of albuminate, the smaller will be the tendency of the chloride salt to give visible evidence of its presence.

Turning for the present from this engrossing subject, we come now to inquire the time necessary for floating papers on the silver solutions.

Under the old system of sensitizing, this subject required some degree of consideration, as it was necessary the time of floating should be regulated by the strength of solution employed; but, with the bath recommended in our last paper, the difference is scarcely discernible, whether floated five or ten minutes, when the due proportions of bath salts are present; this may be ascertained by the solution becoming discoloured or remaining clear; if the former, and the liberated albumen remains freely in solution, there is an insufficiency of soda; if, on the contrary, the organic substance is precipitated, then is there a lack of silver. In either case it would be necessary to shorten the time of floating, although, for results' sake, we strongly advise that the solution be at all times kept in a proper condition. Our usual time of floating is about four minutes. The paper is

then hung up a short time to drain off the superfluous liquid, when the drying is completed, on an ingeniously designed hot-water apparatus, which was invented by the gentleman in whose service we are at present engaged.

The paper having been placed for a few minutes in a damp place, it is now ready for exposure in the pressure frames; it is, therefore, necessary we say a word or two on the subject of printing. The brilliancy of a picture, doubtless, depends in the greatest measure on the quality of the negative, but, at the same time, a bad print may be produced from a good negative. Whilst, under proper treatment, a passable impression may be secured from an indifferent negative. The gentleman amateur, with time abundant at his disposal, if his negatives possess any good qualities at all he should never produce a really bad print, because his field of operations being limited, an opportunity is afforded for studying the peculiarities of each negative, and treating it accordingly. With the professional printer, the case alters. With a large number of frames under his care, but little time can be spared to study the requirements of his negatives; it therefore becomes him to observe an easily practical method. In our printing operations we entertain a decided aversion to direct sun printing, except with strongly contrasted negatives, for it seems to us the reduction effected by a strong light does not produce the fine gradation of light and shade so easily obtained from a good negative in diffused light. Another objection to sun sealding, is its tendency to produce a mottled appearance in the prints; its production is brought about by the bright rays permeating the minute holes which may be seen in the films of most iron-developed negatives, the paper surface in the vicinity of those apertures receiving the strongest light, a proportional amount of extra reduction is effected, which, in the finished picture, bears a strong resemblance to mealiness, because the sheltered portions print lighter. Diffused light cannot penetrate the interstices described; it therefore follows that printing under the last named conditions proceeds more evenly. The day's printing finished, we pass the pictures rapidly through three waters, and they are ready for toning, the theory and practice of which we hope to enter upon in our next "Jotting."

THE TRIPLE ACHROMATIC LENS.

BY J. H. DALLMEYER.

HAVING been requested on several occasions to furnish a more detailed description of the form and construction of my Triple Achromatic Lens than has yet appeared, I take this opportunity of doing so—the more so now, since imitations have lately been put forth by others laying claim to originality.

Before I enter upon a description of the instrument itself, I will briefly refer to its origin.

Some three years since, when reading a paper before the London Photographic Society, entitled, "On the Nature of Distortion," and printed in the PHOTOGRAPHIC NEWS, June 15, 1860, I endeavoured to point out by familiar illustrations the kind of distortion belonging to each of the two groups of view-lenses then commonly used by photographers, viz., the achromatic or single combination meniscus, and the new Petzval combination, called by the different makers orthographic, orthoscopic, &c., &c. At the same time, I also pointed out the fact known to some, that a double or portrait combination, furnished with diaphragms placed between the two combinations in the ratio of their foci, would produce an image approximately free from distortion.

My attention had been called to this subject by a communication from Mr. Rothwell, of Manchester, in which that gentleman showed the possibility of curing distortion in a double combination.

The lens I brought under the notice of members on the above occasion, was a somewhat modified form of portrait-lens, possessing a flatter field of view than others in use at that time, which was provided with stops in the proper

position to ensure freedom from distortion. Thus I endeavoured to supply in one and the same instrument, a portrait and (when used with a diaphragm), a view lens, producing an image practically free from distortion.

How far I succeeded in this attempt is known to those who purchased these lenses, previous to the introduction of my triple achromatic lens in August, 1860.

I experienced, however, soon after the reading of the above paper, and the manufacture of the lens in question, that photographers generally, but more especially amateurs, were chiefly anxious to obtain a lens for views only, which should be free from distortion: and since, in my double combination, alike suitable for portraits and views, the diameters of glasses had to be comparatively large, therefore thick and also expensive (objectionable on both accounts), I was induced to abandon my first idea of supplying the required view-lens, free from distortion, in the form of a portrait combination.

I now turned my attention to a lens referred to in my paper, and in the following terms. Speaking of a double combination with cemented contact surfaces as suggested by Mr. Rothwell, and free from distortion, the field of which was, however, much curved, I observed:—"But being already familiar with the theorem before alluded to, I suggested to my late father-in-law (Mr. A. Ross), that a *negative combination* placed in the position of the stop, would have the desired effect of flattening the field. . . . Mr. Sutton, who had previously given a familiar illustration of the manner of action of Professor Petzval's negative combination, afterwards also suggested the use of such a one to perfect Rothwell's combination."

From this it will be seen that I suggested the use of a negative combination between the two positives for the reason given, and before Mr. Sutton made his suggestions.

But it will readily be admitted that to suggest a combination is one thing, and to carry it out successfully is quite another; and whilst I had obtained nothing whatever in suggestions from Mr. Sutton, in working out the idea, I have never derived any assistance from any one at all.

An incident I cannot forbear mentioning, occurred at this time, which further stimulated my endeavours for a solution of the question. A gentleman well known in several departments of science, called upon me after I had read the paper already referred to, and commissioned me to construct for him, without regard to cost, a view-lens to be free from distortion, which resulted in the production of the "triple achromatic lens," some three months after.

When setting about its construction, I proposed to myself the following problems for solution:—

1. That the instrument should consist of three combinations, two positive and a negative, each of such power, form, and so placed as to cause the refracted, and, finally, emergent pencils, to be parallel to the several incident ones—an indispensable condition for the production of an image free from distortion.

2. That it should be principally available for groups, views, and copying: the largest aperture not to exceed one-tenth or one-twelfth of the compound focal length.

3. That it should be free from spherical and chromatic aberration; each of the three combinations to be achromatic in itself.

4. That it should cover with equal illumination a circular area embracing an angle of 45° and, when stopped down, 60° or more.

5. That the field so covered should be as flat as possible, consistent with moderately good marginal definition.

- 6 (and last). That its cost should be moderate, and not much exceed the price charged for view-lenses then in use. This latter point controlled the expenditure of optical means.

I need scarcely mention that the solution of these propositions was by no means an easy task. Besides the ordinary elementary treatises on optics, I had only the papers by the present Astronomer Royal "On the Spherical and Chromatic Aberration of Eye-pieces," and a few pamphlets by Professor

Petzval to draw upon; but by the aid of these and trigonometrical projections and calculations, afterwards, also, by practical trials, I succeeded, after three months of constant application, in the completion of the "triple achromatic lens," now possessed, without exception, by all the first photographers both in this country and abroad, and which I humbly believe is the best that can be accomplished out of the optical means therein employed.*

The accompanying diagram will facilitate my description.

I will commence by stating that in the sketch the lenses are mounted in what is called a rigid mount or tube; but, as is known, they can also be had in tubes sliding in outer "jackets," and, if required, furnished with rack-and-pinion movement.

A and B are what are called *positive* combinations, both achromatic, and both also externally slightly of the meniscus form or concavo-convex, the radii of curvature being in the ratio of their focal lengths. Assuming I as the focal length for A, that of B is 1.5, their diameters being nearly in the same ratio. The distance or separation between A and B, expressed in terms of focal length of A, is one-seventh of A.

Between A and B, dividing the distance between them in the ratio of their focal lengths, is situated the *negative* combination C; this is also the place for the diaphragms. Like A and B, combination C is achromatic and externally slightly of the meniscus form.

Its focal power (negative), is barely half of A added to B, and its diameter is about two-thirds that of A.

The equivalent focal length of the whole combination is to that of A as 7 to 8.

When requiring to use the instrument for views or copying up to equal size, combination A (the smaller), should always be turned towards the object or landscape, and B (the larger), towards the ground glass of the camera; but, for *enlarging*, the combination should be turned round or reversed, B pointing to the object to be *enlarged*, and A to the screen or sensitive surface in the camera.

For groups and instantaneous effects, the lens should be used with the largest possible aperture, so as to attain the maximum of rapidity; but for landscapes and the like, where time of exposure is of minor importance, smaller diaphragms may be employed, always recollecting that what is called depth of focus, can only be legitimately obtained by the use of small stops.

To ensure freedom from distortion, the camera should be carefully levelled.

I may mention that, if desired, combination C can be unscrewed for cleaning or removal, by first unscrewing combination B; when using A and B alone, the back focus is shortened by about one-half, and consequently rapidity of action is much increased; but, although, achromatic in this condition, the field of view is much more curved, and, except for vignette heads and sitting figures, it should not be resorted to as a portrait lens.

For out-door portraiture, groups, and the like, it is

recommended that the three combinations be used intact, as they are.

In conclusion, I will offer one or two remarks about another new lens introduced, since mine, by Messrs. Harrison and Co., of New York, and sold under the name of "The Globe Lens." Now, without saying one word about the merits or demerits of this instrument (which, by the way, comes a little too late, in supplying what photographers already possess, viz. a "view-lens free from distortion"), it appears to me to be so very limited in its application, on account of the very small aperture necessary to obtain anything like "crisp" or perfect definition even in the centre, that I do not consider it an advance upon my Triple Achromatic Lens.

ONE OF THE CAUSES OF PIN-HOLES IN NEGATIVES.

BY J. W. SWAN.

PERHAPS some of your readers may have been troubled with pin-hole specks, and may be glad to know the cause and the remedy.

The peculiar kind of blemish referred to has the following characteristics. The pin-holes generally occur in a line, exactly opposite to the division where the shutter of the dark slide is hinged for folding.

The cause is *dust* drawn in through the slit of the dark slide in the act of opening the back of it. The opening of the back, especially if it fits closely, operates like the opening of the boards of a bellows, and produces a strong inspiration of air which carries with it any loose particles of dust that may be lodged in the slit of the shutter, and shoots them, in a strong jet, against the surface of the plate opposite. Each particle of dust so deposited forms the nucleus of an abnormal action of the chemicals, and causes a spot or speck.

The remedy is obvious. Have the back of the dark slide slightly reduced in size, so that it fits quite loosely, and be careful to open the slide softly,—not with a sudden pull.

The manufacturers of photographic apparatus ought to be made aware of the facts I have described, and required to modify the construction of their dark slides accordingly.

It is very evident that at present this phenomenon and its cause are either not known, or not regarded, and this is most true of the best class of apparatus, in which the fit of the back is often absurdly made almost air-tight.

PROTO-ACETATE OF IRON AS A DEVELOPING AGENT.

BY M. MC. A. GAUDIN.

Thus far, the best developer with an iron base appears to me to be the proto-acetate. I have frequently failed in preparing it, except by the way of double decomposition, which method is, I think, too irksome for most operators. We know that the protosulphate, so much employed, does not yield very intense blacks; the skies, for instance, always require to be intensified, and even covered with some opaque substance. Pyrogallic acid goes a little farther, but the proto-acetate of iron alone accomplishes our purpose.

The following expeditious method I have found quite successful. Some sulphate of iron and carbonate of soda are pulverized and dissolved separately in a large quantity of water; the carbonate of soda is poured into the sulphate of iron until a precipitate ceases to fall. After leaving the mixture some time to settle, the supernatant liquid is poured off, and the greenish mud is thrown upon a funnel, covered with a piece of moistened linen, folded double; after the water is drained off, a fresh quantity is poured on, and when the draining is complete, the carbonate on the filter is put into a stoppered bottle, or it may be employed at once for making the proto-acetate. To this end, we add a given quantity of *acetic acid*, diluted with water, which reacts upon the carbonate much better than concentrated acid; but this must be done in an open vase, on account of the effervescence

* The draughtsman has not secured quite the proportions of the combination, nor the true figure of the lenses.

and froth produced. In the course of a few hours, stirring the liquid, from time to time, the proto-acetate is made, and may be filtered through paper. It passes through the filter under the aspect of an orange yellow liquid. It cannot be employed in this state, for, upon pouring it on to a negative to develop it, it immediately forms an inky black deposit over the whole surface of the plate. This defect may be completely remedied by adding sulphuric acid, until the brown hue is changed into a greenish yellow. It still frequently causes fogging, although it may have this hue; in that case, a little more sulphuric acid must be added. When at length it leaves the parts not acted upon by light in all their purity, it is sufficient to add a little alcohol, to cause it to spread more readily, and then the solution of proto-acetate of iron may be kept and employed like sulphate of iron, except that it is not necessary to pour it on to the plate so rapidly, or in excessive quantity. Its effect takes place in a few minutes, and the picture may be strengthened indefinitely by adding nitrate of silver of the strength of two per cent., after the acetate, and some acetate after the nitrate of silver.—*La Lumière*.

A LESSON IN PHOTOGRAPHY.—No. 16.*

TANNIN PROCESS.

(Report of a process as practised by Col. Pike, New York.)

The glass plates, as usual in dry-process operations, must be uniform, homogeneous, free from flaws both on the surface and in the material, and flat. The first operation is to abrade the edges all round on both surfaces with a file or emery stone. The second consists in cleaning and polishing the surfaces. New glasses are fixed in the vice; tripoli or rotten stone is next dusted on the surface, and then a sufficient quantity of alcohol is poured upon the rotten stone. With a small piece of rag or Canton flannel rub the surface in all directions, taking up the mixture of alcohol and tripoli as you proceed.

As soon as one side is thoroughly cleaned from all adhering matter, polish the surface with a clean rag, with chamois leather or a silk handkerchief, as may be most convenient; then turn the plate over in the vice and proceed in like manner with the second side. Seizing the plate with a silk handkerchief in the left hand, loosen the screw of the vice and remove all dust from the edges all round, as well as from the two surfaces, and place it away against a wall or partition until a sufficient number have been prepared.

The third operation is to flow the plate with albumen, which is prepared in the following manner:—Take the whites of eggs and beat them up into a perfect froth, and leave the latter to settle for twelve hours or more. To each ounce of the resulting liquid add half a drachm of alcohol and a piece of rock candy as large as half a pea; dissolve the latter and filter. The albumen is now ready to pour upon the clean plates.

Taking each plate in the left hand, between the thumb and finger, grasping the left hand nearer corner, pour a quantity of the prepared albumen on the nearer end of the plate sufficient to cover the whole surface. The albumen thus poured on is spread evenly by means of a long strip of glass about half an inch in width. Holding the glass by one end in the right hand, lay it almost flat upon the albumen, and in such a manner as to press it backwards towards the thumb so as to cover the nearer end of the plate; then, changing the inclination of the glass spatula, press the albumen to the other end, taking care to cover the whole surface; remove the spatula, and pour all excess of albumen by the right-hand further corner into the vial from which it was received. The plate is now put away to drain on a rack, which is constructed as follows:

Take two pieces of wood, half an inch or more in thickness, eighteen inches long, and three inches wide. Beginning at

a distance of half an inch from one end of either piece placed side by side on the table, draw transverse lines parallel with the end across the two pieces, and thus proceed and rule similar lines parallel with the former at half an inch from the preceding. In this way there will be thirty-five parallel pencil lines on either piece of wood.

Next prepare slips of wood three-eighths of an inch in width and an eighth of an inch in thickness. Tack a separate slip on the end of either of the preceding ruled surfaces, parallel with the ends, and with one side coincident, and whose length is equal to the width of the ruled pieces. Tack another piece at the first line, a third at the second line, and so on to the last. In this way there will be a space of one eighth of an inch between each transverse slip.

The next way is to plane two pieces of half-inch stuff, nine inches long and four and a half inches wide. Bisect one of the longer sides of either piece; and from the point of bisection rule a line diagonally to either opposite corner; beginning at each corner and in the direction of the ruled lines, place the ends of either of the pieces containing the tacked-on slips, and nail them in this position, taking care that the slips look upwards. Do the same thing with the other ends.

In this way we have a rack in which the albumenized glass plates can rest between the slips, in an inclined position, so that the excess of albumen can easily drain off, and the plates can dry.

In the operation of albumenizing it is absolutely necessary to have the room as free from dust as possible. This is effected by first wiping all the shelves, doors, boxes, &c., with a wet cloth, and then proceeding over the floor with a moderately wet mop. By neglecting this precaution dust will be apt to settle upon the albumen, and thus produce specks on the subsequent pictures.

In this way the plates are left to dry spontaneously. When dry, they are ready for the fourth operation: they may be kept in this state, however, for an indefinite time.

In the fourth operation each plate is taken separately and gently heated over the flame of a lamp, and then flowed with collodion in the usual way and sensitized in the bath of nitrate of silver, which must be very slightly acid, but never alkaline. The common hath used in the wet process will be quite suitable in the tannin process. The plate is kept in the silver bath until the surface is uniformly of a cream colour, and free from all apparent streaks or specks of oil; it is then taken out and reared on one end in a pail of clean water, with the collodion side towards the centre of the pail, and left there until a second plate is collodionized and sensitized.

Whilst the second plate is in the silver bath we commence the fifth operation, which consists in seizing the plate in the pail from edge to edge between the right thumb and the second finger, and in giving it a sort of wabbling or undulatory motion in the water, so as to wash off all excess of silver; the plate is inclined at an angle of about 45°. Now withdraw the plate from the water, seize the other end in the same manner with the left hand, give it the same sort of oscillatory motion in the water, the other end being inclined downwards. Holding the plate next as when collodionizing, flow the collodion surface several times with pure rain water, and afterwards immerse the plate in a dish of pure rain or in distilled water, until a second plate is ready to take its place.

The sixth step in the tannin process leads us to the truly tannin part, which is properly the preservative part. For this purpose make a solution of tannin as follows:

Distilled or pure rain water	1 ounce
Tannin	15 grains.

Shake well together until the solution is made, then filter. In some cases the filtration is very slow, and consequently requires some time. Do not forget this, but wait until the solution has all filtered through. Some operators add about 20 drops of alcohol to each ounce of the above preservative;

* From *Humphrey's Journal*.

but this is not necessary where the solution is used immediately. Taking a couple of drachms or so of the tannin solution in a separate vessel, as for instance in a small graduated tube, pour it upon the sensitized plate, already thoroughly washed and drained, but still wet from the last dish; let the surplus flow off at the right-hand further corner into the same vessel, and again cover the plate with the solution, and repeat the operation.

The operations of sensitizing and preserving require an artificially darkened room.

The plate is now in a highly sensitive condition, and has to be placed away in a cupboard to which there is no access of either dust or light, until it has thoroughly drained, and is dry. A cupboard is easily arranged for such purposes, as follows:—

Along the back of the cupboard, stretching from side to side, at a distance from the top of 4 inches, screw on a piece of inch stuff, 2 inches wide. At a distance of 5 inches from the left side, bore a hole half an inch in diameter right through, and insert a vial cork, and pare it level with the wood. Proceeding to the right 5 inches, bore another hole and fill it as before with cork; then go on until there is no longer any more room for more corks.

At 4 inches below the preceding, screw on a similar piece of wood to the back of the cupboard. At a distance of 2½ inches from the left side, bore a hole ¾ inch in diameter, fill it with cork, and let the cork project ½ inch from the wood. At every 5 inches, beginning from the first hole, bore others, and fill them in the same manner with cork. In the middle of the first row of corks, insert the quill end of a feather from a fowl's wing, and cut off all the feather part. In the second row insert in each cork a lady's hair pin.

Pairs of similar rows can thus be constructed along the back of the cupboard.

As soon as a plate has been flowed with tannin, and the excess of the preservative solution has drained off, rear it against the back of the cupboard, with the collodion side towards the back, and the lowest side resting on the bend of the first hair-pin, whilst the right side inclines and rests on the first and upper quill. The rest of the plates follow in succession. If necessary, strips of bibulous paper are placed in the hair-pins to absorb the surplus tannin solution, that drips off from the pendant corner. In this way, a large number of plates can be drying at the same time.

If the plates are intended for the preparation of transparent positives for in-door work, or not for immediate use, they may be retained in the drying cupboard until required for use. On the contrary, if required for outdoor work, they have to be piled away in the changing box, whose description could scarcely be understood without a specimen to refer to, and which cannot be manufactured because it is patented. This changing box, however, is an indispensable *vade-mecum* for the dry-plate process; it is ingenious in the highest degree, and exceedingly practical in its application.

The camera and its lens or lenses, together with the plate-holder, ground glass, and changing box, containing a full supply of plates, in addition to a tripod or camera, compose the whole burden of an amateur for a single day's work; these he can carry beneath his arm without being wearied; and with confidence in his workmanship (to be derived from careful experience), he has the satisfaction of knowing that in the evening, when returned to his domicile, his labour will be crowned, nine times out of ten, with success.

Exposure of the Tannin Plate.

The time of exposure varies naturally with the state of the atmosphere and the season of the year. One very important advantage in the dry process is this: there is much wider scope between the minimum and maximum length of exposure in this process than in the wet process; consequently half a minute too much exposure is by no means so injurious as in the latter. With a good light a negative can be taken of a landscape in about one minute or in a minute

and a half; but two or three minutes will produce, in many instances, excellent results.

The tannin process, however, is invaluable in the production or preparation of transparent positives for the stereoscope, by direct contact. The exposure required in this instance is exceedingly short; half or even a quarter of a second in diffused light will be sufficiently long.

Development of the Picture.

The development can take place immediately, or at any desirable or convenient time afterwards. It has not yet been ascertained how long the tannin plates can be kept between the exposure and development; certainly months have elapsed with little or no diminution of effect.

Developer.—No. 1.

Pyrogallic acid	1½ grains
Distilled water	1 ounce
Glacial acetic acid	½ drachm.

No. 2.

Pyrogallic acid	1½ grains
Distilled water	1 ounce
Citric acid	1 grain
Alcohol	12 minims.

Prepare a filter, place on it the pyrogallic acid, and afterwards pour over it the mixture of acetic acid and water; the filtering can be repeated. The plate is first immersed in water for a few seconds, and then flowed with the pyrogallic acid solution. A sufficient quantity is first poured into a proper measure for the development in question; this is then flowed on and off the plate once or twice; afterwards, three or four drops of silver solution are added to the pyrogallic acid, and the mixture is again poured over the plate and kept in motion, until the intensity of the picture is fully brought out. This mixture, when once used, is thrown away as useless, and the plate is washed and fixed as usual in a solution of hyposulphite of soda. The colour of the print is a beautiful rich black; some operators are of opinion that a little chloride of gold will improve the tone.

DEVELOPMENT OF THE PICTURE. (SECOND MODE OF MANIPULATION.)

Stock Bottle, No. 1.

Pyrogallic acid	2½ drachms
Alcohol	2 ounces

Stock Bottle, No. 2.

Citric acid	1 drachm
Nitrate of silver	½ "
Distilled water	12 drachms

When about to develop a picture, immerse the plate for a moment in rain water, so that the surface becomes uniformly moist; then to a drachm of water, add two drops of No. 1, and one drop of No. 2, shake well, and then pour it over the collodion surface, taking care to keep it moving all the while. As soon as the picture has thoroughly appeared, intensify it by adding drop by drop of No. 2 to the developing solution until the shades are sufficiently intense.

TO PREVENT PAPER FROM TURNING RED.

A CORRESPONDENT of *Humphrey's Journal* gives the following as a method of making excited paper keep well, and print with pure whites in hot weather:—

SILVERING SOLUTION.

Nitrate of silver	1 ounce,
Distilled water	5 ounces.

Take 2½ ounces of the mixture; add concentrated ammonia until it clears itself. When the ammonia is first added it will get muddy and dark, but by repeatedly adding ammonia and shaking the solution, it will become clear, care being taken to get in only just enough ammonia; afterwards add the other 2½ ounces of silver and water, also half an ounce of alcohol. Now the solution will be muddy; again shake well and pour into

your silvering dish *without filtering*. If there is likely to be any scum on the top, skim it off with a strip of writing paper, by drawing it across the top of the solution two or three times, using different strips every time.

Now silver the paper by floating from 15 to 30 seconds, but not longer unless the paper is very highly salted. When hung up to dry, the paper silvered with this solution will keep all day without discolouring, unless left on the silvering too long. When the solution gets low, lay aside and make a new one; by so doing several times, you will have enough old solution, by adding them together, to float paper as if you had a new one. Never add a new solution to an old one; but it can be strengthened if necessary; never filter, but clear the solution by skimming as above. In printing, go very deep, as this toning bath bleaches more than any in use. Wash the prints well before toning; soak them in salt and water—proportions: 1 table spoonful of salt to a pail of water; wash again, then tone with the following bath:—

Muriate of Lime Toning Process for Albumen Prints.

Water	16 ounces.
Chloride of gold	15 grains.
Add 5 grains of salt to make acid.			

Neutralize with carbonate of soda; be careful not to make it alkaline, as it affects the action of the gold. Afterwards add

Muriatic acid, C. P.	10 drops.
Chloride of lime, if fresh	3 grains.

If the latter is not fresh, it will take about 5 grains. This bath tones a rich purple black and works very uniform; it can only be used once.

Fixing Solution.

Hyposulphite of soda	$\frac{3}{4}$ pound.
Sub-carbonate of soda	100 grains.
Wash the prints well before fixing.			

Correspondence.

PHOTODIAPHANIE.

SIR,—I beg to inform Mr. Cooper that I have used Ponting's Bristol Varnish for the purpose he names. I should be glad to know of a harder varnish; but it answers very well, and will bear careful washing with soap and cold water. Apply with a good-sized camel-hair brush, then hold to a bright fire until the varnish is set; it may then be coated again, brushing the other way.

The film is easily placed on any part of a vase, if the following simple plan be adopted. Place the vase in a large vessel of water, lift the film out of the basin with a camel-hair brush, and place in the vessel containing the vase; now gently touch the film with the brush to make it float out flat on the top of the water, this may be done in two minutes. If now the point of the brush be placed in the centre of the film and the vase gently raised with the other hand under it, both may be brought out of the water without any tricks on the part of the film. It may be moved with the brush a considerable distance, if this is done directly it is taken out of the water.

In washing, I do not find it necessary to use more than two basins for several films, as they may all be put into one basin whilst the water is being changed in the other. There is no fear of their hurting each other.

I have been induced to make these remarks because I am very much pleased with the process, and find it very much more *simple* than I expected. It answers admirably for stereoscopic transparencies, which ought, therefore, to be produced much cheaper than they have hitherto been.—Yours, truly,
J. BURGESS.

Lower Goat Lane, Norwich.

[Our correspondent mistakes Mr. Cooper's want, we fancy. If we understand him, he wants an opaque, or translucent white varnish, to form the whites when the transferred film is placed on transparent glass.—Ed.]

Photographic Notes and Queries.

THE USE OF A LENS IN PRINTING.

SIR,—The first article in a recent number of the NEWS is no new thing in my experience. For some years I have used it when necessary. At first I used a lens as you suggest; but I found there was a shade produced on the negative, by either my hand or the frame in which I had set the lens.

I remedied this by procuring a small hand convex reflector, and I could thus throw an extra power of light on any part of the negative; and by putting the reflection slightly out of focus, I thus get quit of the danger of burning.—I am, Sir, yours, &c.,
K.

SUBSTITUTION FOR YELLOW GLASS.

SIR,—Since the publication of my letter, some weeks since, respecting the pigments used for rendering glass non-actinic, I have had several gentlemen called upon me, in order to satisfy themselves on the point, also letters from different parts of the country and the continent, complaining that they could not obtain the Japanese gold size anywhere; it is not Japanese, but Japanners' gold size (the former being an error in printing), that is used. Many thought that it contained colouring properties, because it was gold size; but, as you are quite aware, it is not so. The size being merely the vehicle to temper the pigments, and to assist the drying. There are other pigments that contain colouring matter, much more beautiful than raw sienna or orange chrome, when viewed by transmitted light, such as Indian yellow, yellow lake, &c., but they are more or less fugitive, and cannot be depended upon, when exposed to a strong light; whereas, those I have selected are permanent in themselves; the one being earthy, and the other chemical. They cannot, moreover, act injuriously upon each other.

Having been many years an art-student, but finding photography so close to my heels, I felt obliged to take it up and unite it to my profession, and I find, so pleasantly do they jog along hand in hand, that I very much regret I did not embrace it years before; but there is a vast field before us yet, and I hope the time is not far distant when artists will use photography as a companion to painting.

A few days since, a gentleman (an amateur) called in for his carte, and was much surprised to see so much light in my laboratory (a dark room it cannot be called). I referred him to the PHOTOGRAPHIC NEWS. He said he did not take it. I then told him what it was, and what it cost. He was surprised—at the same time sorry—as he had just purchased some yellow glass, and gave as many shillings per foot for it as mine had cost pence. I am glad, sir, that your readers, some of them, are profiting by the hint. Many, no doubt, are still using yellow silk and calico, which does not admit near so much light, and more expensive and liable to fade. When I commenced photography, which I did at the Portland Bazaar, in the spring of last year, I felt no hesitation in adopting the colours named as a substitute for yellow glass; and finding it answered the purpose so well, and did not fade, I thought the hint would be useful to many of your readers; but, on the subject of fading, I was doomed to disappointment, for, one Sunday morning I had the melancholy fact before my eyes that all I was possessed of in the building was fast disappearing before that terrible element—fire—and in less than an hour, negatives, book pictures, apparatus, furniture, and all were gone, not an article was left; so that you were quite right, sir, in saying that I was a severe loser; and, also, I have to thank you for a word in season; but, sir, as I never learnt the art of shivering, I am in consequence a very bad beggar; so I must leave the matter in your hands, with an humble appeal to the generosity of the photographic public to assist one in time of need.—I am, Sir, yours truly,
47, Baker Street, October 6th, 1863. E. ALDIS.

Talk in the Studio.

TRANSPARENT COLOURS FOR PHOTOGRAPHS.—Mr. Burgess, of Norwich, writes—"Some weeks ago, I sent you some coloured portraits, and promised to explain how they were done. Multiplicity of engagements have prevented my redoing the

promise hitherto. I use Judson's dyes, diluted with spirits of wine and water, and mixed to form the various tints required. Wash on the colour, and blot off again with clean blotting paper. The albumen seizes the colour directly, and will not wash off again.

SPOTS ON NEGATIVES.—Among the many difficulties that attend negative making, there is none more vexatious than those troublesome little transparent dots or comets which so frequently mar the beauty of the plates; they are caused by the collodion being alkaline, and may be remedied by adding one drop of saturated tincture of iodine (alcohol added to dry iodine) to each ounce of collodion. Specking, as it is termed, arises from the same cause, and is cured by the same remedy.—*Humphrey's Journal.*

DRY COLOURS FOR PAPER PRINTS.—We have received from Mr. Nowbery, of Longton, a specimen of his method of colouring paper prints with powder colours, from which it appears the tints adhere with great facility, and are then preserved by the application of a suitable varnish. In the hands of persons of skill and taste some very pretty effects may be produced.

BROMO-IODIZED COLLODION AND PYRO DEVELOPMENT.—We extract the following from an interesting private letter from Dr. Hemphill:—"I have read with a great deal of pleasure, and I hope with profit, the long correspondence in your journal about the advantage of iron over pyrogallie acid in the developer, but it seems strange to me that the use of bromo-iodized collodion, with pyrogallie development, appears all but ignored amongst photographers, although the beautiful Eastern views by Mr. Bedford were produced in that way. I have long used for landscape work bromo-iodized collodion (latterly Ponting's or Thomas's), with a developer of pyrogallie acid with acetic and formic acids, the latter not always, and the advantages I supposed to be derived from it were greater rapidity and softness than with iodized collodion and pyro, and greater intensity than with iron; but this year I have used Ponting's bromo-iodized collodion, with a strong iron developer, both for views and portraits, and find that in most cases in a good light I can produce sufficient intensity with the first application only: 30 grains of sulphate of iron, or 40 of the double salt to the ounce. Should you think them worth your acceptance, I will send you in a little time copies of some portraits and landscapes taken in that way for next year's Amateur Photographic Association."

MOUNTING PHOTOGRAPHS.—One of the great troubles of amateurs, who desire to mount a few prints, is the necessity for making fresh starch for the purpose. When they desire a large number of prints mounted, it is wise, as we have often recommended, to employ the professional mounter, than whom we know none more skilful and obliging than Mr. Fox, of Little Britain; but it often happens that the amateur desires to mount one or two, or half a dozen prints. They are not worth the trouble of sending to the professional mounter, especially if the amateur reside in the country, and, moreover, they require to be done at once. Gum has been abandoned as apt to turn acid, and injure the print; glue requires preparation, so does starch. The trouble of preparing either is not great, but it is just sufficient to delay the mounting and make it a bore. What is required is some adhesive material which may be kept always ready for use at a moment's notice, easy to use, efficient when used, and innocuous to the prints. Mr. Hughes, of Oxford Street, has just sent us a bottle of such a preparation, under the name of "Hollis's Opal Mucilage." It answers admirably, spreads smoothly, adheres well, and is clean and pleasant to use. It will keep indefinitely without becoming acid, rancid, mouldy or dry. It is sold in wide-mouthed bottles at 6d. and 1s. It would be a great boon if it were sold in bottles similar to those often supplied with office gum-water; *i. e.*, a metallic top, screwed on, with a brush passing through. Mr. Hughes has also sent us some samples of very excellent mounts with India and fancy tints. These tints are on stout board, not plate paper, to which many photographers object, as being thin and apt to cockle and to break. Also some card mounts with fancy borders: these latter are not to our taste, but they will please some, and are well executed.

To Correspondents.

J. HOLLAND.—Mr. Hardwich's "Manual" is the only work specifically devoted to photographic chemistry.

C. W. L. F.—By the method of "vignetting a picture, and yet having the

ground of a peach colour," we presume you mean the effect produced by double printing, which we have two or three times within the last few months described. The print is vignettted in the usual manner, and then the printed portion is covered with a mask rather smaller than itself, which is kept moving whilst the white grain is exposed to the action of light until it attains a proper depth of tint. This, when toned, possesses something of a peach colour.

HENRY THOMPSON.—We do issue an index at the end of the year; each year's numbers constituting one volume. We also issue a cloth case for binding. 2. There are two methods of obtaining collodion positives on cloth: one consists in attaching the glazed cloth to a glass, and coating and working it in the usual way; and another in transferring the film containing the completed picture from glass to the cloth. There are several ways of doing this: a very simple one consists in pouring on the completed picture a little alcohol, containing a few drops of nitric or sulphuric acid to each ounce, and the same mixture on to the surface of the cloth; place them in contact, and rub down to expel air-bubbles; place in a pressure-frame, and when quite dry, the cloth may be lifted away, bringing with it the picture. 3. As an enlarged copy from a glass positive, the print you enclose is very good indeed. 4. Photography is, we believe, very successful in Australia, but whether there is there an y better opening for a skilful photographer than at home, we cannot tell.

MEXICO.—Sea air will not affect negatives properly packed. You will not, we believe, have to pay any duty.

HOLLAND.—We believe each of the collodions you name are good; but we should prefer the second on your list. 2. For paper, the last mentioned. 3. For lenses, the first on your list.

AN IGNORANT AMATEUR.—After completing your development, and carefully washing, you may take your negative into diffused light to fix. If you do not obtain sufficient intensity in the face, it may arise either from the use of an unsuitable collodion or from not having the face well lighted. You may easily obtain sufficient force by intensifying again after fixing.

J. BELDON.—The letter was duly addressed and forwarded.

T. P. E.—The only method you can adopt is to separate the ashes as carefully as you can from the sulphide, and all that cannot be removed must go into the crucible, and will be separated there.

OMNINO VICTOS.—We have never seen round insensitive spots so large as a quarter of an inch in diameter. The only suggestion we can make is that you have probably dropped some solution on the plate from the bottom of one or other of the vessels used in some part of the process. 2. It is always difficult to state the exposure which ought to be given, so much depends on the exact nature of the light and the illumination of the object; but it is quite impossible to do so without knowing what aperture you wish to use. You state that the lens has a focus of 15 inches, and the diameter 3 inches; but you omit to mention the stop.

T. R. II.—We have no personal knowledge of any one who takes microphotographs. A few weeks ago we inserted, in "Answers to Correspondents," the address of a gentleman, Mr. Jaglis, who, we believe, undertakes the work.

A.—You cannot very successfully undertake to bleach shellac yourself, but you may purchase it, perfectly white, of almost any chemist. The process, however, renders it very difficult of solution. Varnish-making requires more appliances and more experience and skill than most amateurs possess. The addition of an essential oil after such as that of spike or lavender facilitates solution. A variety of circumstances influence the best proportions.

HARRISON FRODSHAM.—The substitute for yellow glass, referred to in No. 253, was given under the head "Notes and Queries," in No. 258, PHOTOGRAPHIC NEWS. If you wish to try the formula in 261, substitute for Orleans, orange chrome.

II. PIRETT.—See answer above.

XENOPHON.—Your portraits are, as they have been pronounced, "pretty good for the work of an amateur." The chief fault is a little tendency to hardness, arising probably from a little over-intensification. The best are 3 and 5, both of which are good pictures; 1 and 6 would probably be good if they were well printed and toned. You must take more care to get an even film, and so avoid many irregularities in the background.

J. A.—We have not had much experience with the leuses in question; but what we have is not very favourable. 2. Unless you pile up the deposit by means of silver and pyrogallie acid very rapidly and so coarsely, it ought not to sensibly injure the sharpness of your image. Try to master that method, it is the safest plan for general use.

AQUA PURA.—We are not familiar with the powder enclosed. 2. You may, probably, be able to obtain a description from the firm named. Several Correspondents in our next.

Reviews of Wilson's New Stereographs, Dr. Hemphill's Views in Ireland, Sutton's Volumetric Analysis, and Brother's Portraits of Engineers, together with several articles in type, are compelled to stand over until our next.

STRENGTH OF THE PRINTING BATH.

THERE is no subject of greater importance to the photographer than the proper strength of the silver solution used in printing. There are two aspects in which the question claims attention—the artistic and the economic. It is of primary importance that the best results possible from the negative should be secured; and it is necessary that these results should be obtained at the least possible waste of the precious metal. Perfect results must not, in any degree, be sacrificed to economy; but there should be no expenditure which is not accounted for in the results obtained. The subject of the discussion at the last meeting of the North London Photographic Association is, therefore, worthy of a more extended and experimental attention.

The question really resolves itself into this:—What is the minimum strength of silver bath with which the maximum of excellence in printing may be obtained? There are three distinct operations to be performed by the nitrate bath in exciting albumenized paper. It has to render insoluble, or "coagulate," the albumen; to convert the soluble chloride combined with the albumen into chloride of silver, and to supply the requisite proportion of free nitrate of silver necessary to rapid and vigorous printing. Any strength of solution which performs these offices, or any of them, imperfectly, will yield bad prints, and fail in securing the primary end of printing. Any proportion of silver present more than is necessary for these ends is wasteful, and fails in securing the second condition, economy.

The advocates of strong baths advance various reasons, many of which are very cogent. First, in regard to the process termed "coagulation," they state that this, is rapidly performed before the water in which the silver is dissolved can exercise any solvent action on the albumen, whilst a weak solution attacks the albumen at once, and dissolving part, not only robs the paper of some surface and brilliancy, but also rapidly contaminates the nitrate bath. That the strong bath converts all the chloride present into chloride of silver rapidly, and so requires a short floating, by which the sensitive salts are largely kept on the surface, and an important condition of brilliancy secured. That the proportion of free nitrate necessary for good results being an uncertain quantity, is at least made safe by the use of a strong bath. And finally, that practice demonstrates the advantages of a strong bath in prints of greater force and brilliancy than can be obtained by a weak solution. These are the chief arguments they advance as to the value of strong baths in securing the first condition, good results; and in regard to the second condition, economy, they urge that all the silver not actually used in producing the image may, by care, be recovered, if the various residues be properly preserved.

The advocates of weaker solutions simply affirm the strong ones to be unnecessary, and therefore wasteful. That the albumen may be rendered insoluble by solutions of twenty or thirty grains to the ounce, instead of sixty, eighty, or a

hundred grains. That the whole of the chloride may be converted into chloride of silver by a longer floating on the weak solution, as easily as by a shorter floating on a strong solution. That the necessary proportion of free nitrate is supplied by the weak solutions, and that practices demonstrate the sufficiency of the weaker solutions in all cases where paper and judgment are used.

On the score of safety, the advocates of strong baths have doubtless the best of the argument; but if satisfactory conditions can be defined, there is no need to go to an excess to secure safety. Strong solutions do unquestionably rapidly "coagulate" the albumen, and thus prevent any portion from being dissolved; they also permit a short floating, and thus prevent the silver solution from soaking so completely into the paper. Whether this keeps the image so perfectly on the surface, as is sometimes imagined, we are not so sure. This, we conceive, is really more affected by the mode in which the first preparation of the paper is managed, for if the chloride employed have sunken into the paper, it is quite certain that, however short the floating, the silver will follow it. If the paper be new, the size readily soluble, and the floating on the albumen not very rapidly and skilfully performed, the salt will penetrate into the body of the paper, and the silver will follow it, forming as much of chloride of silver in the paper as on its surface. If, on the other hand, a paper be used, the sized surface of which has become hard and firm by age, and if the albumenizing be managed with the rapidity and skill which forms a good surface without allowing the solution to penetrate or soak into the body of the paper, then short floating on the silver bath, will preserve the sensitive coating entirely on the surface, and secure the desired object. The objection to long floating, mentioned by Mr. Shadbolt, is more important. He suggested that if the nitrate of silver soak into the paper and enter into combination with the size, a compound is formed which is difficult to eliminate, and conducive to decomposition and fading.

The question as to the proportion of free nitrate necessary to good results is the most difficult to decide. Its exact office is not well understood. We know that nitrate of silver is not itself reduced by light, and that pure dry chloride of silver alone is insensitive to light; we know also that even when it is in combination with organic matter, if all free nitrate of silver be washed away, it darkens slowly under the action of light; and we know that chloride of silver, in the presence of free chlorine, is insensitive to light. If paper prepared with chloride of silver only, without free nitrate, be exposed to light, it darkens slowly; but as the chloride of silver is reduced by light to a metallic state, chlorine is liberated; so that, after the first action of light, we have chloride of silver and the presence of free chlorine, and consequently a delayed and imperfect action results. If free nitrate of silver be present, it is stated by some that the chlorine liberated, attacks the nitrate, and forms a fresh supply of chloride of silver to add vigour to the image. If this theory be correct, then the proportion of free nitrate

should bear a specific relation to the amount of chloride, and heavily-salted papers would require a larger proportion than lightly-salted papers. Practice alone can, however, satisfactorily determine the proportion of free nitrate which will secure the best results.

The specimens exhibited by Mr. Harman, at the North London meeting, appeared to be, within certain limits, tolerably conclusive. They consisted of a series of prints from the same negative—a somewhat thin one, produced under similar conditions in all respects, except the strength of the nitrate bath, and the time of floating. They were excited as follows:—

No. 1	nitrate bath	10 grains,	floated	10 minutes.
No. 2	"	20	"	10 "
No. 3	"	40	"	5 "
No. 4	"	60	"	3 "
No. 5	"	80	"	2 "
No. 6	"	100	"	45 seconds.
No. 7	"	120	"	15 "
No. 8	"	160	"	5 "

All were exposed under the same negative in sunlight, and toned, &c., together in the same solution. It was difficult to form the most correct estimate by artificial light; but there appeared an unquestionable progressive improvement. The last were certainly better than the first, but it was doubtful whether the progressive improvement was very definitely marked on those higher than sixty grains. The printing of those from the weak baths was said to be slower, and the loss, or reduction, in toning and fixing considerably greater than with those excited on the stronger bath. Mr. Dawson had examples of a few experiments which pointed in the same direction.

On the other hand, Mr. Hislop showed some prints produced from paper excited on a weak bath, which were in no wise deficient in vigour. At intervals during the last two or three years we have received from a very intelligent photographer and highly cultivated gentleman, signing "N," communications on this subject, accompanied by some exceedingly charming specimens, produced on a bath of about twenty grains to the ounce. Mr. Sutton has recently suggested that with a thirty-grain bath, to which a few drops of lemon juice had been added, he obtained on his patent albumenized paper results equal in vigour to those excited on a bath three times that strength. And we have during the present summer, been experimenting with printing baths not much exceeding twenty grains from which we have obtained excellent prints.* Mr. Blanchard, whose prints, whether landscape or portrait, are amongst the best we know, informs us, that after using for some years very strong solutions, the conclusion to which experience has conducted him, is that a uniform strength of forty grains to the ounce gives the most satisfactory results.

Perhaps the most important phase of this subject has yet to be developed. In addition to the prints already mentioned, Mr. Harman exhibited three others, produced on paper excited on a bath containing twenty grains of nitrate of silver and sixty grains of nitrate of soda to each ounce of water. These prints were equal in vigour and richness to the best of those produced on the simple silver bath, however strong. This method of partially substituting nitrate of soda for nitrate of silver was first suggested by a correspondent of the *Photographic News*, signing "Publicola," in April last, who forwarded to us some fine examples of its

* The bath here referred to was slightly acid with nitric acid; but since this article was written, we have carefully tested, with Mr. Hart's volumetric apparatus, a neutral silver bath, from which we had just been obtaining some prints as excellent in all respects as we could desire; brilliant, rich, and free from meanness. About a pint of solution was made for the purpose of experiment early in the summer, the strength being 60 grains to the ounce. This had been used without any renewing until it was reduced to about one-third of its original bulk, remaining neutral and giving fine prints. We were prepared to find it weak, but, on carefully testing, we were surprised to find that it contained only a fraction above 20 grains to the ounce, the exact strength being 20 1/10th grains. The prints last produced were on various samples of paper, and all gave good results. They consisted of Lanpray's (Sutton's patent), Hart's, and Elliott's.—Ed.

value at the time. Since then, our contributor, "A Photographer's Assistant," has been working successfully in the same direction, and has forwarded us some most unexceptionable prints. It is not, of course, supposed for one moment that the nitrate of soda takes the place of a salt of silver in forming the image, but its presence seems to facilitate in some way—upon which we shall have something to say on another occasion—the formation of a vigorous image, and by the prevention of waste, materially economises the working. Even where residues are saved, there is a loss in the process of recovering the silver; and amongst amateurs the various residues would frequently cost more to collect than they would yield: so that the less free nitrate finding its way into washing and fixing baths, the better.

As we said at the outset, the subject generally will well repay further experimental inquiry. We have here endeavoured simply to lay a simple statement of the case, as it now stands, before our readers. For our own part, we have generally counselled the use of strong baths, as giving, with indifferent negatives, and most kinds of paper, satisfactory results. But it is probable that when the conditions are well understood, it will be found that, with moderately intense negatives, a considerable saving may be effected in cost without any sacrifice in results.

Critical Notices.

A SYSTEMATIC HANDBOOK OF VOLUMETRIC ANALYSIS, OR THE QUANTITATIVE ESTIMATION OF CHEMICAL SUBSTANCES BY MEASURE. By FRANCIS SUTTON, F.C.S. London: Churchill.

The practice of photography has conducted largely to increase the amateur study of chemistry; and as analysis by the volumetric method commends itself to the amateur from its comparative simplicity, and from the obviousness of its results which are all apparent to the eye, this work will be especially welcome to the intelligent photographer. Mr. Sutton, whose name is identified by photographers with an excellent manufacture of neutral chloride of gold, has here endeavoured to supply an existing want in the shape of a simple and trustworthy text-book, embodying the experience of the best authorities in this branch of chemistry. We believe this aim has been carefully and conscientiously carried out; the arrangement of the book is excellent, and the style simple and clear.

The experimental photographer is well aware of the importance, as a basis of operations in arriving at just results, of estimating the true value or strength of the agents he is using; and he will find the most valuable aid in obtaining this knowledge, always assuming that he has at least some elementary knowledge of chemistry to begin with, as this is not a book for beginners. On another page we give Mr. Sutton's mode of estimating silver solutions, and we refer the reader to the volume itself for the methods of examining various other important agents used in photography.

ALBUM PHOTOGRAPHS. By G. W. WILSON. Marion and Co., Soho Square.

MR. WILSON has recently issued a large number of his old photographs, as well as those of the present season, in a new form, suitable for preservation in albums especially prepared for them. The size is 4 1/2 inches by 3 inches, and Messrs. Marion have provided for them a most elegant 4to album, with apertures on each page of the dimensions we have named. Important amongst the recently published pictures are an admirable series of Windsor's fine old Castle and its surroundings, and some fine cathedral interiors. To say that these pictures are by Mr. Wilson is to imply that they are admirable specimens of photography and art: that water, and cloud, and atmosphere, as well as foreground, are well rendered; although some of the interiors

are, perhaps, open to exception on the score of converging uprights produced by tilting the camera.

In a few instances, Mr. Wilson informs us, the globe stereo lens was used. Of the qualities of these lenses he remarks: "They are a little slow in working in consequence of requiring to be filed with a very small stop; but they cover a much larger field than the ordinary single lenses, and it was for this reason, and for the purpose of getting straight lines, that I used them. I tried a larger globe lens of about the same focal length as the No. 1 triple, but I preferred the work of the triple; and, indeed, if Mr. Dallmeyer would make a pair of triple lenses of about $4\frac{1}{2}$ inches focal length, they would do all the globes do, and more." For ordinary stereo landscape, in which a wide angle is generally unimportant, Mr. Wilson prefers his single lenses.

There is another feature of interest to name: Messrs. Marion issue these prints coloured as well as plain. We have rarely seen anything in the shape of colouring applied to photographic landscapes which has not in our eyes spoiled them; but here the colour is applied with so much judgment, taste, and skill, just doing sufficient and no more, and that in the right manner and the right place, that an exceedingly fine and natural effect is in many instances secured, and a real beauty added to the pictures. The album is one of the most chaste in design and excellent in construction we have seen.

PHOTOGRAPHIC ILLUSTRATIONS, Selected from the Abbeys, Castles and Scenery of Clonmel and the surrounding Country. By W. D. HEMPHILL, M.D., F.R.C.S.I. Clonmel: J. H. O'Neill.

DR. HEMPHILL has here produced a beautiful little album for which Irish tourists will thank him, and has set an example which we hope many photographers residing in picturesque districts will follow. We have a couple of dozens of charming vignette views, card size, mounted in an album prepared for them, and duly provided with title-page and descriptive index, which gives completeness and interest to the volume. Many photographers are familiar with Dr. Hemphill's photographs from exhibitions; these views are selected with fine artistic feeling, and photographed with skill. The album is also at once good and chaste.

A GROUP OF TELEGRAPHIC ENGINEERS AND OPTICIANS, Photographed by A. BROTHERS, Manchester.

WE have here one of those marvels of composition portraiture, in which Mr. Brothers delights and excels. Twenty-nine gentlemen, whose names are prominently associated with the progress and improvement of the electric telegraph, are here harmonized in one satisfactory group, and all excellent portraits. Prominent in the picture are many well-known faces, whose names will be remembered whenever the engineering triumphs of this age are mentioned. Here are Robert Stephenson, Sir Charles Bright, Professor Wheatstone, Cooke, Ricardo, Latimer Clark, Bouelli, Ewart, and a variety of others. The difficulties in producing a group of this character appear at first sight well-nigh insurmountable. Besides the necessity of obtaining the negatives at different times, when and how it might be convenient to the sitters, nine of them could not sit at all, so that Mr. Brothers had to make use of such copies of photographs as he could obtain. But from these heterogeneous materials, twenty gentlemen sitting at different times, and nine copies of portraits, a group had to be arranged which should do justice to each, and at the same time compose a satisfactory and artistic picture. The completed result, however, shows no trace of the difficulties of producing it; the grouping is simple, easy, and natural, and possesses at once unity and harmony. And notwithstanding the thirty-two printings necessary to produce the original group, no appearance of defective photographic result can be traced in the published

prints. Such photographic triumphs are every way creditable, and we trust that the publication will be as successful as the production is worthy.

STEREOGRAPHS OF THE ENGLISH LAKE SCENERY. By R. J. SPROAT.

THIS series comprises some of the most charming stereographs we have seen, the beauty of the subjects receiving full justice in the perfect photography. The water is transparent, the foliage clear and detailed, and the cloud and atmospheric effects exceedingly beautiful. Ullswater, from Bonass Hotel, No. 80, is a most exquisite picture. Derwentwater Bay and Causey Pike, No. 105, are also exceedingly fine. Windermere Lake, from near Lowwood, No. 100, possesses one of the most perfect banks of clouds we have ever seen rendered, the slide only being removed from perfection by the unfortunate position of a figure in the foreground. Otter's Isle, Derwentwater, No. 107, is wonderfully perfect, as is also the quiet beauty of Grassmere, from Red Bank, No. 99. The perfect rendering of cloud, water, and foliage we find here is very rare, and we shall be glad to learn more of Mr. Sproat and his method of working.

**JOTTINGS FROM THE NOTE-BOOK OF A
"PHOTOGRAPHER'S ASSISTANT."**

No. V.

TONING OPERATION.

THE subject proposed for discussion in the present paper needs no argument to prove its importance, nor does it require a flourish of language to arrest the attention of the photographic reader, whether amateur or professional, as all, by bitter and temper-trying experience, have been taught, that a necessity exists for a more extended knowledge of the principles involved in our toning operations, as under existing conditions the successful issue of preceding labours hangs tremblingly on the satisfactory working of the gold solution, when the prints are exposed to its capricious and oft-times treacherous action.

The changes by decomposition that occur in toning solutions are under the guidance of certain fixed laws, somewhat complex in their operation, but easily brought under control when the governing principles are understood. To attain this knowledge, it is necessary that we begin at the beginning, and end where the researches of many have commenced.

Men are usually too high-minded to submit to the necessity of stooping or creeping when occasion requires; hence little truths are passed over, and they commence their labours at the wrong end, and, as a necessary consequence, tantalizing failures meet them at every turn.

From an early period of photographic history, gold, in combination with chlorine, has been employed to impart a satisfactory finish to the appearance of sun prints; and when employed in union with hyposulphite of soda, its operation seemed to be all that need be desired, but as that tell-tale, time, wended on its swift-winged course, facts were unravelled whose evidence could not be allowed to pass unnoticed. The once beautiful surface of the paper began to assume the changes which ultimately led to the destruction of all for which it was held valuable—yellow! green! fading! gone!! And the lovely image that had so often delighted our eyes was vanished for ever; and, in our despair, we pronounced hypo-toning to have proved itself a deceitful and villanous failure, and as such was cast aside to give room for the newly introduced alkaline process, whose flattering promises caused the knell to be sounded for its yellow-faced predecessor, whilst photographers exultingly clapped their hands to welcome the stranger, through whose instrumentality tones were to be secured as permanent as they were beautiful. But, alas for human hopes! this promising new comer speedily proved

itself to be the most mischievous of all mischief-making imps. By the practice of what was called "dolges," it could sometimes be coaxed into a good humour, and then its thrice happy director would cry, "Rejoice with me, all ye my photographic brethren; give the prints a good ducking, and a few more grains of soda to the imp, and he will work like a Briton." But long ere the printer's echo had ceased to attract attention, the soda bribe had lost its efficacy, and the creature was then said to be suffering from some atmospheric change which had impaired its delicate organization; so, batch after batch of prints, with plague-stricken faces, would be thrown aside, and more propitiations times hoped for. These, with a thousand untold troubles, have, from the first, attended toning operations.

Commencing with the hypo-toning bath, we purpose taking a rapid glance at the various agents which, up to the present time, have secured a recognized place in our gold solutions, when we hope to prove that in all cases the general principles by which decomposition is effected are alike in action, although they are found to vary in detail.

Hyposulphite of soda in symbols is rendered thus—

that is to say in each atom of the substance named there exists one part soda, one of hyposulphurous acid, and five water. When an ordinary sun print is exposed to the action of the first-named salt in solution, a portion of the hyposulphurous acid separates from its base and passes over to the unreduced silver, and an hyposulphite of the metal is formed— $\text{AgO, S}_2\text{O}_5$. This process of decomposition calls into action the chloride of gold, Au, Cl . A portion of the chlorine passes over to the soda and the liberated gold takes up a new lodging on the surface of the immersed print. The chief advantage gained by this method of depositing the gold is an entire immunity from mealiness, and it becomes us to inquire into the conditions which prevent the evil; but, ere we proceed in this direction, we wish it to be understood that our remarks on this and every accession are tendered with a spirit untinged with dogmatism, whilst explaining our own views we are at all times open to correction, if proved to be in error.

The affinity that exists between the unreduced silver and the hyposulphurous acid causes one atom of the last-named substance to separate from its base to unite itself with one atom of the metal; this union sets at liberty one atom of soda to attract and combine with the freed chlorine, and common salt is produced. Now, a careful study of these changes at once shows us the reason why hypo toning yields no mealiness. By the action of the fixing salt, the free and unreduced silver is at once removed, and with it all tendencies to engage chlorine in its biting operations, consequently the bleaching agent yields to another source of attraction and unites with the soda, leaving the liberated gold to pursue its course unmolested. If no other interfering agent presented itself, hypo toning would be perfection itself, but, unfortunately, free acid is introduced with the gold, whose superior prowess upsets theories by its dangerous practices, the worst of which is its tendency to set sulphur at liberty; and it frequently happens that a print is sulphur-toned instead of receiving a more abiding colour from the inert gold present in the solution. It may be asked from what source is the sulphur produced? In reply, we would point to the fact that a strong acid will at all times overcome a weak one, and the soda being in combination with the lowest oxide that can exist in the scale of acids, the union is one of the weakest characters, so that no difficulty is experienced in procuring its freedom, and whilst at liberty by some other decomposing, but not undisturbed, process, it yields a colour so like that given by gold that one can scarcely be distinguished from the other.

Theoretically chloride of gold, entirely minus free acid, should in the hypo bath yield permanent tones; but, considered practically, would toning action be set up under those conditions? We believe not although we leave the

question open for those who practice hypo toning to determine; if they answer in the affirmative, then we ask, Does it pay to practice this worn-out system? Without fear of contradiction, we say it does not. A few months ago we were engaged in an establishment where the hypo toning was adopted, and five drachms of the expensive gold salt were consumed in toning 25 to 30 sheets of paper; with our lime and soda solution we would undertake to produce a better tone at an expense of 12 grains of gold for the same number of sheets; and this assertion in itself, we presume, to be argument sufficient to induce every photographer to cast aside his old-fashioned notions, if he has any, and take his place in the race of progressive improvement.

RAPID TESTING OF COLLODION.

BY M. MC A. GAUDIN.

To ascertain whether, by employing the collodion, silver bath, and developer we have prepared, we can obtain blacks in our negative proportionate to the luminous impression, we must place side by side on the same piece of glass very different degrees of exposure; to obtain these by the aid of a single candle would require the counting of a minute or more. We can easily obviate this by causing diffused light to fall during five seconds upon the reverse of the sensitized glass, partially protected by a small piece of oil-cloth cut into a triangular shape, by removing a black screen which covers an opening of about two inches in diameter: then, after having slightly displaced the triangle of oil-cloth applied to the back, we again count five seconds, holding the plate inclined vertically at about two inches from the candle; after again removing the piece of oil-cloth a little, we again count five seconds at two inches from the candle, and then pour the developer upon the sensitized surface. If the three ingredients employed are good, we shall be able to distinguish four perfectly distinct spaces upon the plate; one very black, corresponding to the exposure of five seconds to diffused light, plus the ten seconds to the candle; the second, much less intense, but strongly marked, corresponds to the ten seconds exposure to the candle; the third, half as marked as the second, corresponds to the five seconds exposure to the candle; lastly, the fourth space, corresponding to the absence of exposure, should appear under the form of a small triangle, having perfectly retained the opaline tint peculiar to sensitized collodion without any fogging.—*La Lumière*.

NITRATE OF AMMONIA.

BY CARL MEINERTH.*

SOME six months ago Mr. Anthony communicated (page 302) a process of modification for the nitrate of silver bath by the use of nitrate of ammonia. I have tried it with excellent success, but would wait for reports from other quarters before putting my own forward. As nothing, however, has appeared yet, I beg to offer the result of my experiments and appreciation of Mr. Anthony's liberal contribution.

The term "nitrate of ammonia" seems, to the superficial observer, so much the same thing as the photo-household word "ammonio-nitrate," that we should not wonder if some persons mistake the former for the latter. So a correspondent says, that he took notice of Mr. Anthony's suggestion, but that it had occurred to him six months before: and then he goes on describing the old process of preparing the ammonio-nitrate of silver bath for albumen, as given by Waldack, and recommended by Colman Sellers and other writers in your Journal two years ago.

[When I was reading that article, the nitrate of ammonia which it contained—or rather did not contain—seemed to decompose, and filled me with laughing-gas.]

* From *Humphrey's Journal*.

But I did not see Mr. Anthony's idea in that light. I believed he meant the common salt, nitrate of ammonia—which I sometimes use as a stimulant in watering my plants—and with it I proceeded as follows:—

In 14 ounces of pure water dissolve 1 ounce of nitrate of silver, and in 2 ounces of water 60 grains of nitrate of ammonia. When both are perfectly dissolved, mix together, shake well, and filter.

This gives a 30-grain silver solution, and, after the paper was silvered (1½ minute) and fumed in the ordinary way, yielded prints which came black from the printing-frame and changed but very little in the toning (acetate) and fixing-bath. I send specimens from the second dozen of sheets silvered on the same solution.

[The tone of the specimens sent is very agreeable, of rich purple, such as we have a right to expect from sensitization in a bath of ammonio-nitrate of silver, or in one of nitrate of ammonia and nitrate of silver. There is a difference between these two baths *sometimes*, not always. Let us examine, for instance, the composition of the bath of ammonio-nitrate of silver as recommended by some authors. The requisite quantity of nitrate of silver is dissolved, and the solution is divided into two equal parts as soon as the oxide of silver is all dissolved by the cautious addition of ammonia, which first produces the oxide and then dissolves it. Now what is the composition of the solution at this stage? Is it nitrate of silver and ammonia? Certainly not. We will be more definite and begin again. Add ammonia to the solution of nitrate of silver as long as a brownish precipitate is formed, and remove the latter by filtration. This precipitate is oxide of silver which has been separated from the nitric acid, whilst the nitric acid, by reason of its greater affinity for ammonia, has formed a new salt—nitrate of ammonia holding in solution a certain quantity of the oxide. If now the remaining oxide be dissolved in ammonia and added, we shall have a mixture of nitrate of ammonia and of ammonia holding in solution oxide of silver,

This mixture is divided, as said at the beginning, into two equal portions, to one of which nitric acid is added until it shows an acid reaction. Now, what are we to infer from this? That the ammonia has combined with the nitric acid so as to form nitrate of ammonia with a slight excess of nitric acid, and holding in solution also the oxide of silver. The two solutions are again mixed, upon which we have:

Nitrate of ammonia and ammonia holding in solution oxide of silver, in which the nitrate of silver has entirely disappeared.

In the nitrate of ammonia bath we have:

Nitrate of ammonia and nitric acid holding in solution oxide of silver.

Here there is a difference; but take the case where only one-third of the solution is precipitated, and in which the oxide is afterwards dissolved by ammonia, and then the two solutions are mixed. The formula will stand now—

Nitrate of ammonia and nitric acid holding in solution oxide of silver.

Together with a variable quantity of nitrate of silver and oxide of silver.

Here there is an addition, but scarcely a difference, practically speaking.

From this rationale it is evident that the nitrate of ammonia bath is more rational, if equally good in its toning properties, from the fact that there is no loss of oxide of silver.—Ed. *Humphrey's Journal*.]

PHOTO-BLOCK PRINTING.—Mr. Duncan Dallas, the inventor of a new system of photo-electric engraving, yielding the most perfect results as yet attained in that direction, has recently been enabled to apply his process to the production of engraved blocks, containing the image in relief like wood cuts, capable of being printed at the ordinary printing-press, in conjunction with type.

ON THE BEHAVIOUR OF CHLORIDE, BROMIDE, AND IODIDE OF SILVER IN THE LIGHT, AND ON THE THEORY OF PHOTOGRAPHY.

BY HERMANN VOGEL.*

AMONGST the numerous important discoveries of the present century, interesting in a scientific, industrial, and social point of view, photography occupies one of the first places. Invented by Niépce and Daguerre only twenty-four years ago, it has advanced from year to year, improvement following improvement, until its productions have now attained a perfection by which they leave all graphic art far behind them in truth to nature. In the same measure, the application of this art has extended into all possible departments, so that now, there is scarcely any field in the visible world into which it may not enter with advantage. It draws (by nature printing in the widest sense), the pictures of living persons; it furnishes faithful representations of animals, plants and minerals; it fixes the grand natural scenery of our earth, as well as the pictures of stars distant from us, millions of miles; it notes the course of the barometer and thermometer. The grandest works of art are rendered by it cheaply accessible, even to the poor, in copies inimitable in their fidelity, and by this means it becomes as important an agent in the culture of the people in the department of art, as is the art of printing in the domain of science.

But, although photography has made such advances, the development of its theory has not kept pace with the practice; certain as its different manipulations have become, we are just as uncertain in the interpretation of many of the physical and chemical processes taking place in them. Many attempts have indeed, been made in this direction, by Schnauss, Hardwich, Davanne, Girard, Monckhoven, and others; but still the theories hitherto proposed, do not suffice to explain all the mysteries and to settle the disputes which have lately arisen with regard to the nature of various photographic processes.

These circumstances have induced me to undertake a series of new experiments, and to repeat various experiments of former investigators. For three years I have been occupied in these researches, and in the present paper, I publish the first part of them. But, before passing to the experiments themselves, I must give a more exact account of the task which I set before me, and for this purpose, describe briefly, in the first place, the photographic manipulations which are now in use.

For the purpose of taking a picture, the photographer coats a glass plate with a thin film of collodion, impregnated with iodides and bromides (of potassium, sodium, lithium, cadmium, &c.); this plate is then sensitized, that is, immersed in a neutral or acidulated solution of 1 part nitrate of silver, in about 10 parts of water (the silver bath), and taken out again in about two minutes. The plate then presents a layer of collodion impregnated with iodide and bromide of silver and free solution of nitrate of silver. In this state it is put into the camera obscura, and exposed for a time to the light. The plate still shows no trace of a picture. This only makes its appearance, when an acid solution of sulphate of iron is poured over it, in the dark chamber. The sulphate of iron mixes with the silver solution adhering to the plate, and produces a precipitate of granularly pulverulent silver, which is deposited on those parts of the stratum of iodide of silver, which have been acted upon by the light, and thus renders the picture visible (*the so-called developing process*). The negative picture thus brought out, which consists merely of separate granules of silver (just as a lead pencil drawing of distinct granules of graphite), is now washed, and an acid solution of pyrogallic acid and nitrate of silver is poured over it; by this means a pulverulent precipitate is again formed, which is deposited upon the picture already existing, and renders this darker (*the strengthening process*). The picture thus obtained is washed; hyposulphite of soda is then poured over it, by which all the iodide of silver is dissolved (*fixing*), and it is again washed. In this condition, the picture forms a *collodion negative*, which is employed for the production of *positive pictures on paper*. For this purpose, paper soaked in common salt, and coated with white of egg or arrowroot, is floated upon a solution of nitrate of silver, and dried; the paper thus impregnated with chloride and nitrate of silver, is covered with the varnished negative, and exposed to the light. The light then shines through all the transparent parts of the negative, and gives the subjacent paper a brown colour; whilst the parts of the paper

* Poggendorff's "Annalen."

lying under the opaque portions of the negative remain colourless. In this way, is produced a positive picture, which is washed with water, put into a very dilute solution of gold, and finally fixed with hyposulphite of soda.

Of the processes here described very briefly, the scientific explanation of the process of exposure and of the action of the developing fluid was the problem that I set myself in the first place to solve; and here the following three questions arose:—

1. How does light act upon pure chloride, bromide, and iodide of silver?

2. What influence upon this action is exerted by foreign substances, such as water, acids, free salts of silver, organic bodies, &c.?

3. What change do the silver compounds which have been affected by the light, undergo during the so-called developing process?

The answering of these questions includes the answers to many others, which will come up in the course of the description of the following experiments.

1. How does light act upon pure chloride, bromide, and iodide of silver?

For the solution of this question many experiments have already been made, especially with respect to the chloride, fewer with regard to the iodide, and fewest in connection with the bromide of silver.

Scheele was probably the first (in 1777) to study the action of sunlight upon chloride of silver. He stated that chloride of silver blackens in the light of the sun, and leaves metallic silver when treated with ammonia; from this he concluded that it is decomposed in the sunlight into chlorine and silver. He further stated that under strong nitric acid it remains white.

A. Vogel and Wetzlar found, however, that blackened chloride of silver cannot be deprived of its colour by heating with nitric acid, and that by this means no silver is dissolved; from this they concluded that chloride of silver is decomposed by the sun's light into chlorine and subchloride (Schweigger's Journal, Bd. lii. p. 446).

Wetzlar, moreover, asserted, in opposition to Scheele's statement, that chloride of silver blackens even beneath nitric acid. Like Wetzlar, Wittstein found that no silver is extracted by nitric acid from blackened chloride of silver; and from this he also deduced the formation of a subchloride (Buchner's Report, Bd. xxxvi. p. 170).

Robert Hunt, on the contrary, maintains the formation of metal upon the surface of photographic paper impregnated with chloride of silver, as also the production of $Ag^2 Cl$ and of oxide of silver!

Guthrie (Chem. Soc. Am. Journ. x. p. 74) and Draper (Phil. Mag. xiv. p. 322) come to a different conclusion. They assert that the chloride of silver is decomposed into Ag and Cl. Guthrie thinks that the separated silver assumes a passive state, and is therefore insoluble in nitric acid. Draper says that, as nitric acid is incapable of dissolving any silver out of chloride of silver that has been exposed to the light, the free silver thus produced is endowed with such altered properties that one might believe in a transmutation of the metal!

Spiller (Humphrey's Journal, vols. xviii. and xix.)* affirms that, by the long-continued action of light upon chloride of silver, a body is produced the specific gravity of which is favourable to the notion that Ag Cl, when exposed to the light, is decomposed into Ag and Cl. Malone makes the same assertion. Starting from Faraday's opinion that the red colour of a solution of gold mixed with phosphoric ether is due to the suspension of red metallic gold, he thinks that a red and a brown silver may also exist, and supports his opinion by the fact that, when a solution of phosphoric ether is added to one of nitrate of silver, a brown fluid is produced resembling in colour papers impregnated with chloride of silver and rendered brown by exposure to light.

In order to ascertain the action of light upon chloride of silver, Dawson made a series of experiments. He exposed to the sun for three months bottles containing a solution of nitrate of silver to which he gradually added a dilute solution of chloride of sodium, and also other bottles with chloride of sodium, to which he added some solution of silver every day; he then washed the precipitates which had been rendered brown by the sun's light and boiled them with nitric acid. He found that the acid extracted silver from all the precipitates, without, however, essentially changing their brown colour. From this he concludes that the final action of light upon chloride of silver con-

sists in the formation of metallic silver. but that it previously passes through several intermediate stages, and that $Ag^2 Cl$, $Ag^3 Cl$, $Ag^4 Cl$, &c., were formed one after the other (*British Journal of Photography*, September, 1862).

Davanne and Girard likewise maintain the decomposition of chloride of silver into Ag and Cl, but do not support their view by any new facts (Davanne, "Chimie Photographique," 1861, p. 423.)

Hardwich, on the contrary, maintains the formation of a subchloride (Manual of Photographic Chemistry, 1863, p. 23).

These statements, to which I might add many others, show sufficiently how divergent are the opinions as to the change which chloride of silver undergoes by exposure to the light.

As to the alterations to which bromide of silver is subject is subject under the action of light, Berthier has stated that this substance acquires a pure grey colour, and blackens more slowly than chloride of silver (Poggendorff's Annalen, lxxvii. p. 417).

Monckhoven, on the contrary, asserts that it acquires colour more rapidly than chloride of silver; and he adds that the chloride becomes blue, and the bromide grey, on exposure to light (*Photographic Notes*, August 1862).

Iodide of silver has been the subject of fuller investigations. The change of colour of iodized silver plates was observed by Daguerre and others. Moser asserts that the iodized silver plates undergo no chemical change on exposure, and in proof of this cites an experiment made by Draper, who placed an iodized silver plate in the sun with moistened starch-paper, when the plate became dark green, but did not betray the smallest trace of free iodine (Poggendorff's Annalen, lvi. p. 190).

According to Moser, the entire change undergone by iodide of silver during exposure consists in its being blackened, and acquiring the property of condensing vapours of mercury. He also states that when the sun acts for a long time upon iodized silver plates, these again become pale (*loc. cit.* p. 185).

Schnauss has published some important investigations upon the part played by iodide of silver in photography (*Archiv der Pharmacie*, lxxiv. p. 1). He also supposes that iodide of silver is not chemically changed by the action of light, but that it only acquires the property of attracting reduced particles of silver by virtue of "a peculiar electrical tension." He proved that by means of iodide of silver alone no photographic picture can be produced, and that this was developed only by a precipitate of silver, which deposits itself on the exposed portions of the iodide of silver.

Subsequently he positively established, by experiment, what had long before been conjectured from various photographic processes, namely, that there are two modifications of iodide of silver—one sensitive, and the other non-sensitive; that the iodide of silver which is precipitated from a solution of silver by an excess of iodide of potassium is not sensitive to light, and that only that precipitated from an excess of silver solution is effected by exposure (*Photogr. Archiv*, 1860, p. 115). He says, iodide of silver of the latter kind becomes brown in the light. He seems, however, to think that iodide of silver owes its photographic properties only to the presence of a trace of nitrate of silver, which cannot be got rid of even by long washing. He regards the compound $Ag I + Ag ONO$, which may be obtained in a crystalline form from solutions containing iodide of silver, as the essentially sensitive body in the above described photographic processes (*Photogr. Nachschlagebuch*, pp. 144, 180, &c.). He also supposes that a chemical decomposition of iodide of silver, with elimination of iodine and formation of subiodide, takes place after long exposure (*loc. cit.* pp. 75 and 144). Sutton also maintains the indifference of iodide of silver prepared with an excess of iodide of potassium, and is opposed to its chemical decomposition. He supposes pure iodide of silver to be indifferent to light, and thinks that its sensitivity arises only from a trace of nitrate, which remains even after long washing (*Photographic Notes*, August, 1862.) [He thinks, however, that chloride and bromide of silver are reduced to silver with evolution of chlorine and bromine. Davanne asserts that iodide of silver is decomposed by light into iodine and silver (*Chimie Photographique*, par Barreswille et Davanne, p. 82). Hardwich and Monckhoven have combated this view with sound reasons (*Photogr. Archiv*, 1863, p. 79).

I have thus given a summary of the most important statements extant upon the changes produced by light upon the salts of silver, although I have by no means exhausted the literature of this subject, and many opinions not mentioned here will be

* Extracted from the PHOTOGRAPHIC NEWS.

discussed further on. I now pass to the description of the experiments which I have made for the solution of the question under investigation.

(To be continued.)

ANALYSIS OF THE SILVER SOLUTIONS USED IN PHOTOGRAPHY.

BY FRANCIS SUTTON.*

THE silver bath solutions for sensitizing collodion and paper frequently require examination, as their strength is constantly lessening. To save calculation, it is better to use an empirical solution of salt than the systematic one previously described.

This is best prepared by dissolving 43 grains of pure chloride of sodium in 10,000 grains of distilled water; each decem (=10 grs.) of this solution will precipitate 0.125 grn. (i. e. $\frac{1}{8}$ grn.) of pure nitrate of silver; therefore, if 1 fluid drachm of any silver solution be taken for examination, the number of decems of salt solution required to precipitate all the silver will be the number of grains of nitrate of silver in each ounce of the solution.

Example:—One fluid drachm of an old nitrate of silver bath was carefully measured into a stoppered bottle, 10 or 15 drops of pure nitric acid and a little distilled water added; the salt solution was then cautiously added, shaking well after each addition until no further precipitate was produced; the quantity required was 26.5 dm., = 26½ grains of nitrate of silver in each ounce of solution.

Crystals of nitrate of silver may also be examined in the same way, by dissolving (say) 30 or 40 grs. in an ounce of water, taking 1 drachm of the fluid and titrating as above.

In consequence of the rapidity and accuracy with which silver may be determined when chromate of potash is used as indicator, some may prefer to use that method. It is then necessary to have a standard solution of silver, of the same chemical power as the salt solution; this is made by dissolving 125 grains of pure and dry neutral nitrate of silver in 10,000 grs. of distilled water; both solutions will then be equal, volume for volume.

Suppose, therefore, it is necessary to examine a silver solution used for sensitizing paper. One drachm is measured, and, if any free acid is present, cautiously neutralized with a weak solution of carbonate of soda; 100 dm. of salt solution is then added with a pipette; if the solution is under 100 grs. to the ounce, the quantity will be sufficient. Three or four drops of solution of chromate of potash are then put in, and the silver solution delivered from the burette until the blood-red colour of chromate of silver is just visible. Suppose that 25.5 dm. have been required, let that number be deducted from the 100 dm. of salt solution, which will leave 74.5 dm., or 74½ grains to the ounce.

This method is much more likely to give exact results in the hands of persons not expert in analysis than the ordinary plan by precipitation, inasmuch as with collodion baths, containing as they always do iodide of silver, it is almost impossible to get the supernatant liquid clear enough to distinguish the exact end of the analysis.

Recent Patents.

APPARATUS FOR TAKING PANORAMIC PHOTOGRAPHS.

THIS specification of invention by J. R. Johnson and J. A. Harrison, was sealed in March 1863. We give the provisional specification, the final statement being too lengthy and elaborate for our columns.

Our invention consists of certain improvements in the apparatus for taking panoramic pictures. It is well known that if a photographic lens be mounted vertically upon a pivot, the centre of which coincides with a vertical line drawn through

the true centre of the lens, and if such lens be made to turn upon the pivot, the images of the objects which are brought in succession in front of the lens during its revolution may be projected upon a screen placed behind the lens, and if such screen be part of a cylinder, the radius of which is equal to the focal length of the lens for the images so projected, and the centre of which coincides with the centre upon which the lens turns, such images are true representations of the objects, and remain stationary upon the screen, notwithstanding the motion of the lens; cameras thus constructed have been used for producing panoramic pictures upon curved daguerrotype plates. It is also known that if instead of the curved plate for receiving the images a flat plate be employed, and if while the lens and the base upon which it is mounted and which carries the plate revolve, the plate be made to traverse in the opposite direction, with due relation to the rotation of the lens, the images projected upon the plate are likewise stationary; cameras formed upon this principle have been suggested for the production of panoramic views, but so far as we are informed have not come into practical use. Now, the object of our invention is to render both the above-mentioned forms of camera fit for use with the modern process of photography.

Our improvements consist, 1st, of an improved construction and arrangement of the parts of the flat plate camera, so that their motions are smooth, equable, and free from vibration, and so that the whole apparatus is rendered more compact and portable.

2nd, Of a new mode or modes of obtaining the relative motions of the lens and sensitive plate, such motion being obtained directly by mechanical means, instead of forming "guide curves" by trial, as has before been proposed to be done.

3rd, Of an improvement in the gearing when working both forms of camera.

4th, Of the application of a spring or falling weight to give the motion to such cameras, and of means for regulating the motion both at variable and invariable rates.

5th, Of an expanding diaphragm to regulate the exposure in cameras moving at an invariable rate.

6th, Of an expanding diaphragm to be placed between the lens and picture, by means of which sky and cloud effects may be obtained.

In effecting our first improvement we render the camera symmetrical and duly balanced by placing the lens in its centre instead of at one side, and placing the rollers or other support upon which it rotates at equal distances on each side of the centre, and upon the circumference of a circle whose centre coincides with the centre of the pivot upon which the apparatus turns, so that the space travelled over by each roller is equal, and the resistance consequently equal. The plate-holder slides within the camera instead of through its side.

In its simplest but least compact form, the camera is an oblong box placed upon a plate or bed upon which the rollers revolve, as shown in the diagram No. 1, in which the dotted lines indicate the plate-holder and its line of motion, and also the motion of the rollers upon the bed. It will be seen, therefore, that the whole apparatus has a motion of rotation round the pivot placed under the centre of the lens, while the plate holder has a motion of translation from one end of the camera to the other. We render the camera light and more compact by dispensing with the vacant space, as shown in the diagram No. 2, the dotted lines indicating the condensed form. The camera proper then assumes very small dimensions, the necessary length for the traverse of the plate being obtained by a tube or narrow box attached to the back of the small camera; the weight may be still further reduced by substituting a plate or thin board for the tube just described. The plate-holder slides upon the plate, which acts at the same time as a dark slide, see diagram No. 3. We can still further limit the dimensions of the apparatus by shortening this plate, and letting the plate-holder overhang or extend beyond the back plate at each end, in which case provision must be made for shutting out the light, which may be effected by a strip of india-rubber cloth or oiled silk passing over rollers, see diagram No. 4, placed at each end of the plate-holder.

2nd, We obtain the relative longitudinal motion of the plate to the rotary motion of the lens and camera, when a flat plate is used, by a toothed wheel fixed on the bed or plate, upon which the camera turns, gearing into a rack attached to the plate-holder; but to obtain this effectually, the wheel must be wholly or partially within the camera, or the plate-holder must

* From *The Handbook of Volumetric Analysis*, by FRANCIS SUTTON.

slide outside, as in that form of camera previously described and shown by diagrams 3 and 4. By this modification of the apparatus the motion is obtained in a direct manner, and the necessity for the trials or experiments to form the guide curves is dispensed with, as is also a large amount of friction from the rollers which act upon the curves. We find, however, that a much smoother and more equable motion is obtained by employing a fixed disc or pulley instead of a toothed wheel; a cord or strap is attached at one end to the disc, and at the other to the plate-holder. As the camera revolves, the cord or strap winds upon the edge of the disc, drawing forward the plate-holder for a distance equal to the segment of the arc of the circular edge of the disc upon which the cord or strap has wound itself. Or the cord or strap may be attached at each end to the disc respectively, and be passed over from rollers, as shown in the diagram No. 5. The plate-holder is fastened to the cord or strap, and slides backward or forward according to the direction in which the camera carrying the rollers rotates.

3rd. Our third improvement consists in adding a fly wheel or other regulator to the gearing for working panoramic cameras, by which a greater uniformity of motion is produced.

4th. In order to obtain definite exposure with wet collodion or other quick-acting processes, especially in obtaining the so-called instantaneous pictures, we find that the due rapidity and equality of motion cannot be obtained by hand. We therefore adapt a spring or weight to move the apparatus. With a weight or spring the rate of motion may be made invariable or variable. We obtain an invariable motion by a fly-wheel escapement, or by any other mode of obtaining motion at a fixed rate. In this case it is necessary to adjust the rate of exposure by the amount of light admitted; to effect this we form an expanding diaphragm by making openings in two plates of metal having motion in opposite directions by means of a right and left-handed screw, or otherwise. In one position the openings on the plates coincide, and the full aperture is obtained; but when moved in opposite directions the resulting opening becomes reduced, and at last closed. The diaphragm thus formed is placed within the tube of the lens, and by this means any amount of aperture within certain limits may be given, and the amount of light adjusted. A variable motion may be given to the apparatus proportionate to the amount of exposure required by a fly or vane, the arms of which may be set at a varying angle, or by other known modes of adjusting motion; we prefer, however, for this purpose a tube or small cylinder fitted with a piston, the two ends of which are in communication by a pipe; the rod of the piston passes through a stuffing box, so that the tube may be kept full of water, or any other fluid. A cock or valve is placed within the pipe which joins the two ends of the tube or cylinder, by adjusting the cock or valve the aperture may be increased or diminished at will, and thus the rate of the passage of the fluid from one end of the tube to the other under an equal pressure of the piston, and consequently the rate of motion of the latter may be regulated; such a regulator may be attached directly to the string of the falling weight, or by a rack fixed to the end of the piston gearing into a toothed wheel attached to the pulley over which the cord passes. Any rate of motion may be thus obtained.

5th. We fix a diaphragm between the lens and sensitive plate close to the latter, as in the curved plate camera. We render this opening of the diaphragm variable by forming it of superposed plates of metal which slide over each other, so that the form and size of the opening may be changed at will.

Proceedings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

The usual monthly meeting of this Society was held on the evening of Wednesday, the 21st, in Myddelton Hall. Mr. G. SNABOLT in the chair.

The minutes of a preceding meeting having been read and confirmed, the following gentlemen were elected members of the Society:—Messrs. G. Cartland, jun., A. Saunders, and H. P. Clements.

Mr. Dawson stated that the sub-committee for selecting the presentation print had communicated with Mr. Wilson, but owing to his arrangements with his publishers, Messrs. Marion and Co., he was unable to treat directly with them. On

applying to Messrs. Marion and Co., Mr. Bishop, of that firm had met them in a most handsome spirit, offering a couple of the $7 \times 4\frac{1}{2}$ prints at the mere cost of printing and mounting; and to avoid delay, allowed them to select from their stock the full number they required. The prints were on the table for members to make a selection of two copies each.

A choice selection of Wilson's well-known cabinet photographs were produced, and distributed to the satisfaction of every one.

A vote of thanks to Messrs. Marion was passed by acclamation.

The CHAIRMAN exhibited one of the new albums by Marion and Co., filled with Mr. Wilson's charming album views.

Mr. Dawson exhibited a number of pleasing and artistic card portraits, chiefly of children, illustrating the power of photography to secure expression, by Messrs. Ross and Thompson, and some pleasing studies of larger size by the same artists.

Mr. F. W. HART exhibited his apparatus for estimating the amount of precious metal in the salts or solutions used in photography, and illustrated its working. It consists of a burette, something like Mohr's alkalimeter, the markings dividing it into sixteen equal parts, the whole containing exactly one ounce avoirdupois or $437\frac{1}{2}$ grains. The burette is furnished with a compression stop-cock of vulcanized india-rubber, permitting the dropping of the solution to be easily regulated. The clip or pinch-cock is an improvement, in simplicity and efficiency, upon Mohr's. The burette is provided with a convenient support or stand. A sealed tube is filled with an accurately-weighed portion of pure dried chloride of sodium, which when added to eight ounces of distilled water, measured in the burette (ordinary graduated measures rarely being accurate), gives the test solution. A pipette, holding one drachm, is provided for drawing from the stock bottle of nitrate of silver solution an accurately measured drachm. This is placed in a larger vessel, and added to about six times its bulk of distilled water, together with a few drops of nitric acid. An ounce of the test solution is now placed in the burette, and a portion of its contents dropped into the silver solution to be tested. If one division of the burette be emptied in precipitating the whole of the silver as a chloride, the solution has contained 8 grains to the ounce; two divisions, 16 grains to the ounce, and so on in proportion. The illustration of the method of estimating the amount of silver in a given sample of waste was as follows: a sample of 15 grains of dried waste, purporting to be chloride of silver, was placed in a test tube with an equal weight of pure zinc; upon this was poured about a quarter of an ounce of dilute sulphuric acid, one part of acid in eight of water. The nascent hydrogen formed by the decomposition which followed uniting with the chlorine, threw down the silver in a metallic form. When this operation was completed, and the silver well washed, the addition of dilute nitric acid converted the silver into nitrate of silver, which was tested in the manner above described, and was found to yield $9\frac{1}{2}$ grains of nitrate of silver, which, containing about 63 parts in each 100 of pure silver, gave about 6 grains in the sample of waste tested. The burette, support, test-tube, box of pure zinc, tube of pure chloride of sodium, &c, all packed neatly into a small mahogany box.

Mr. HARMAN, in accordance with a promise given at the last meeting, produced a series of prints from the same negative, printed on paper excited on silver baths of different strengths. The paper was prepared expressly for the purpose by Mr. Hart, with pure undiluted albumen, containing eight grains of salt to each ounce. The negative which was produced was one of moderate quality. The first two prints were floated for 10 minutes, one on a 10-grain nitrate bath, and the other on a 20-grain nitrate bath; the next for 5 minutes on a 40-grain bath; the next for 3 minutes on a 60-grain bath; the next for 2 minutes on an 80-grain bath; the next for 45 seconds on a 100-grain bath; the next for 15 seconds on a 120-grain bath; and the last for 5 seconds on a 160-grain bath. A progressing increase in vigour and richness was found up to 80 grains; beyond that, the results seemed doubtful. He also exhibited some prints from the same negative, excited on a 20-grain bath, containing 60 grains of nitrate of soda, according to the formula suggested by a correspondent of the PHOTOGRAPHIC NEWS, six months ago. These were equal to the best of the others. All the prints were exposed in sunlight on the same day, and subjected to the same treatment in toning and fixing. Those excited on the weak solutions of simple nitrate were slower in printing and lost

more in toning and fixing than the others. Those which received long floating showed the image right through the paper whilst wet, whilst the others having the imago more confined to the surface did not do so. Those floated on the very weak bath seemed to show that a portion of the albumen was dissolved.

The CHAIRMAN remarked that the results appeared certainly in favour of the strong solutions, but what were the commercial results?

Mr. HARMAN said that if the residues were carefully saved, there was not much loss by using strong solutions.

The CHAIRMAN said the results precisely agreed with the opinion he expressed in the printing committee years ago. Then as to the use of the two salts, what was Mr. Harman's conclusion?

Mr. HARMAN said the process must be a great advantage if a 20-grain silver bath gave results equal to a 60-grain silver bath.

The CHAIRMAN remarked that since there was not a less actual expenditure of silver there was not much advantage, as the bath would only require renewing so much more frequently.

Mr. WHARTON SIMPSON said that the recovery of silver from residues always involved some actual waste besides the trouble, and therefore all the free silver that could be dispensed with effected some saving. But, as it often happened that amateurs did not save their washing water, &c., the saving to them would be considerable, besides involving less expenditure at the outset, a consideration where large baths were necessary.

Mr. HISLOP had felt the question to be a very important one when he last month called attention to it, and to amateurs it was of vital consequence. He had often thought that the subject had been treated in a dogmatic manner without careful examination, and he thought that the specimens brought before them proved that a great deal too much stress had been laid on the importance of strong nitrate baths, for there was, after all, but very little difference between the prints produced by the weakest and by the strongest bath described; certainly not nearly so much as between the various strengths employed; whilst, when nitrate of soda was employed, the difference quite disappeared. Then as to the question of waste, as Mr. Simpson had very properly put it, amateurs were especially concerned. They rarely saved their waste; they had not the appliances for doing so economically. Their printing was done at odd times, now a little and then a little, and often put aside altogether for a time. He had been led to examine the subject by some recent observations by Mr. Taylor, and he found on experiment that good prints could be produced by the aid of solutions much weaker than those generally said to be imperative for good results. The bath must, of course, be strong enough to decompose the chlorides; but the great excess of free nitrate was, he felt convinced, unnecessary. The question was, how much nitrate of silver was necessary to produce the necessary changes. They had not yet got to that result, but he thought it was established, that with proper care good prints could be produced by a much less expenditure than formerly, and he thought few would continue to make baths of the old strength, if one with several ounces of silver less would do. He thought his views had been amply confirmed by the specimens produced.

Mr. HARMAN thought there was all the difference in the prints he had produced, between bad and good.

Mr. HISLOP did not see this; he thought none very good.

Mr. HARMAN said the negative was not very good; but the best prints were as good as could by possibility be produced from the negative.

A desultory conversation ensued on some vigorous prints, produced by Mr. Hislop with a weak bath, and on the methods of printing weak negatives, &c.

Mr. DAWSON produced some prints taken with a view to test this subject. The paper was prepared expressly for the purpose, 12 grains of chloride of ammonium being used to each ounce of albumen; thin Saxe, medium Saxe, and thick Saxe, each being tried on various baths ranging from 30 to 90 grains. There was a decided progressive improvement in depth and vigour in those excited on the strong baths. With the thin Saxe, however, no improvement was observed after passing a strength of 60 grains; whilst, with the thick Saxe, the best results were obtained on the 90-grain bath. Those excited on the 30-grain bath require five times as long to print as those on the 90-grain bath. He had also tried nitrate of soda, using a 45-grain silver bath; he found no difference whatever in the prints produced with that bath and with a portion of the same solution without

the nitrate of soda, and both were inferior to those from a stronger bath. As to time of floating, he found that with the thin and medium Saxe a short floating on a 60-grain bath was better than longer; whilst, with a thick paper, five minutes was better than two minutes. With thin flat negatives he used a weak solution, and printed in the shade.

The CHAIRMAN and Mr. SIMPSON both remarked that for weak negatives they would use a strong solution, and print in the shade, and for hard negatives, use a weak solution, and print in the sun.

A conversation ensued as to the precise meaning of the term weak negative, and some other matters, and the subject was dropped.

Mr. SWAN exhibited some of his new crystal miniatures and the Chairman explained to the meeting the principle upon which they were produced, as described in Mr. Swan's paper at the British Association. After some conversation on the subject,

Mr. MARTIN exhibited some fine photographs of Balmoral, and other Scottish scenery, and portraits of the Prince and Princess of Wales, taken by Mr. Stephen Thompson. The collodion was Horno and Thornthwaite's bromo-iodized, the lens for the landscapes, Dallmeyer's triple, and for the portraits, the No. 1 B. of the same maker.

The CHAIRMAN exhibited some of Mr. Bourno's photographs, taken in the East, and a specimen of Mr. Dallas's photo-electric engraving.

Mr. COLLIS, of the firm of Ottowill and Co., exhibited a clever and well-made repeating camera for medallion portraits, taking twelve negatives with four lenses.

Mr. W. W. King promised a paper on the tannin process for the next meeting.

The proceedings then terminated.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, October 28th, 1863.

PHOTOGRAPHS in their natural colours! This dream of the ardent photographer has been realized by M. Charlot Plé; that is, if the news be true. Be that as it may, M. Plé is committed to the fact of the discovery, for the Minister of Public Instruction transmitted to the Academy, at its sitting of the 28th ult., a note from M. Charlot Plé, concerning the discovery of a substance which permits the obtaining photographic pictures, *reproducing the colours of the objects represented*. This note, however, does not make known the composition of the bath into which the paper is immersed to impart the properties claimed for it, and therefore the Academy has no means of proving the truth of this discovery. The author of it, it is true, offers to give, if desired, all the necessary details, and, at the same time, some proofs obtained by his process. It would have been much more satisfactory, if he had done so at once, without waiting to be asked. Before the Academy appoints a committee of inquiry, M. Plé will have to give satisfactory evidence of the integrity of his discovery.

M. Balsamo, professor of physical science at Lucca, has communicated to *Cosmos* the composition of a new bath for positives. He says:—"The employment of the salts of gold has now become very general in photography; we know that the effect of their action is to transform the pale tints the positives, obtained by salts of silver possess upon leaving the fixing bath, into artistic tones.

"Operators have long endeavoured to compose toning baths with the salts of platinum and mercury, which would permit a variety in the hues of the proofs. None of these baths give the velvety tint peculiar to the salts of gold, and so agreeable to the eye. I have been induced to study the characteristics of the salts of bismuth employed as toning baths, and I have obtained, especially with the nitrate of bismuth, proofs with very fine tones, the hue of which may be compared with that of the skin of the chestnut. This toning bath deeply penetrates the blacks of the proof,

leaving the half-tones transparent. There is an important precaution to be observed in practice, as is well known, the nitrate of bismuth produces, with water, an insoluble sub-salt, which alters the proofs, if it be not dissolved by means of acetic acid, which does not injure the delicacy of the proofs.

M. Balsamo adds, that by varying the manipulations of his process, he can obtain a great variety of hues, imitating crayons. The proofs have undergone no change during the two years that have elapsed since they were printed. Two new metals have recently been discovered. One by MM. Reich and Th. Richter, in the arsenical pyrites of Freybourg, to which they have given the name of *indium*, because there is no green ray in its spectrum; but, on the contrary, an indigo blue ray, which hitherto has not been seen in the spectra; it is very brilliant and clearly defined, and very persistent, with a refrangibility much greater than the blue ray of strontium.

The other new metal has been discovered by a Swedish chemist, M. Bahr, in a mineral resembling orthite, found in the isle of Roensholm. He has given it the name of *wasium*, and the mineral he calls *wasite*. It does not appear that it gives characteristic spectral rays.

M. Soulier, partner of M. Ferrier, has added 200 more stereoscopic views in Switzerland to his already large collection, numbering now over 5,000 views. The new series depicts the scenery of the cantons of Lucerne, Unterwald, Uri, Tessin, the Grisons of Saint Gall, Thurgovia, the duchy of Baden, and the Tyrol.

Paraffin possesses certain properties which render it useful in the laboratory. It may be advantageously substituted for oil in baths, as it endures a high temperature without evaporating or emitting any unpleasant odour. Filtering paper, after being soaked in it, may be kept several weeks in concentrated sulphuric acid without undergoing the slightest alteration. From this property of paraffin it may be advantageously applied as a coating to labels on bottles containing strong acids: fluoric acid even does not act upon it, except it be heated. Paraffin appears also to be useful in preserving fruits. Apples, pears, &c., coated with it retain all their freshness during several months.

Recent analysis of the water of the Dead Sea show the presence of an extraordinary quantity of bromine, nearly $\frac{1}{2}$ grains in every ounce of water; and if ever a large demand for bromine arises, an inexhaustible supply presents itself in the waters of this great lake.

PHOTOGRAPHY IN COLOURS.

Canandaigua, New York, Oct. 10, 1863.

MY DEAR SIR,—Yet in the country, I cannot be expected to write you any news from the photographic world. I am immensely busy about these times, in an extensive investigation of the manner in which gentlemen having nothing to do spend their time. I fell over a waterfall fifteen feet high, a short time since, and in consequence of a dislocated jaw-bone and a disabled arm, have been prevented from photographing since; so I take long walks sometimes, and feel lonely without my camera. Lying flat on my back on a log in the wild woods on a sunny afternoon, when I had walked some miles away from home, I fell to ruminating on the vicissitudes and uncertainties of our art. A chip-squirrel pranced along a limb over my head with a huge butternut in his paws, and disturbed a bright red leaf, which fluttered and whirled around, till, at last, it settled on my nose. Too lazy to brush or blow it off, I looked at its transparent colours. I looked at the gorgeous trees above me, and at the varied hues of the woods in the swamp at the foot of the lake. "Oh!" cried I, in a sudden paroxysm of earnest feeling, which frightened the chip-squirrel off his perch, and made him drop his nut; "Oh! for the man who can photograph in colours."

Our forests in America are gorgeous in October. Yes,

they are *gorgeous*, and this word only approximates to an idea of their many-coloured hues. The shade most predominant, perhaps, is flame colour, or "magenta." Then comes the rich yellow and scarlet of the maples; the "Sauds of Sahara" shade of the beeches; the deep brown of the oaks; the red of the creeper vines; all backed up with the deep green of the cedars and pines, or the still verdant chestnuts which are among the last to change. Oh! for the undiscovered art, Chromatic Photography! "Pshaw," said I, as I closed one eye, and looked at the poor worthless maple leaf with the other; "Pshaw, what is photography if it cannot picture this one miserable leaf, which we trample under foot!"

I puffed the leaf spitefully away, and flopped myself off the log, resolved to return home and punch out both the eyes of my camera, and empty all my chemicals in the street gutters.

Mr. Editor, where is the genius of man? If we can call the sun to draw out for us all the forms and shapes of both art and nature with more accuracy than our own hands can do it, why can we not induce him by liberal drafts on chemistry, to reproduce colours? Let all the "irrepressible experimentalists" of the whole photographic world bend their energies to this one end, and let there be no rest until it is attained. For until this can be done, we are but as the caterpillar of the dirty path, and we cannot yet understand the brilliantly coloured butterfly state, to which we must at some time arrive. Hoping some lucky and patient professional or amateur will soon publish to the world a short and easy formula for taking *instantaneous* impressions on dry plates, comprehending all the natural colours; and feeling confident that some such man is going to soon turn up, I will postpone the demolition of my apparatus for the present.—Yours respectfully,
F. F. THOMPSON.

CHEAP BATTERY FOR THE ELECTRIC LIGHT.

SIR,—In the last number of your valuable paper, I see the electric light mentioned as having even greater actinic powers than the sunlight, but the immense cost of such a combination of cells as is mentioned, renders their use in practical photography impossible.

Now, there is a way to produce an electric light with one cell only, but having the intensity of 20 to 30 cells, by means of the Ruhmkorff Induction Coil. The cost of this light would be about 3d. per hour. I am not aware that any experiments have been made to find out if this light can be made useful for photography; from what I have seen of the light, I should think it might be useful for printing at least, possibly even for portraiture, and might in this case become very valuable to the London photographers in the approaching season of dullness.

I may mention that the cost of the whole apparatus would be £6 to £8, I think.

If any of your readers should like to make experiments, I shall be happy to give the address of a maker of batteries and coils, where they may be got cheap—possibly, for the first experiment, on hire.—I remain, Sir, yours truly,

London, October 27th, 1863.

ARGENT BISCH.

Photographic Notes and Queries.

FRAUDULENT CHLORIDE OF GOLD.

SIR,—From the enclosed, you will see that I am a maker of photographic chemicals, and I beg to address you on a subject which deserves consideration, viz., the article chloride of gold for toning. Feeling convinced, from the many valuable hints you give to photographers, that it is your study to assist them with all useful information.

I have noticed for some time that many artists, after giving a tube with full weight of fine dry crystals of chloride of gold "a fair trial," pronounced it not better than a tube of moist salt, which was evidently adulterated with soda. I was always

convinced that the judgment of such artists was at fault, but I was not aware that the adulterations of the above article were as extensive as they really are, according to the October number of the *Pharmaceutical Journal*, which I beg to send you, and from which you will see that there is a very large proportion of gold tubes in the market, warranted to contain 7 grains of gold, but which contain only about 5 grains.

Now, if a photographer cannot find out the difference between a tube containing 5 grains, and another containing 7 grains of gold, his manipulation must be wrong, and he must waste about one-half of the contents of the latter tube, which waste must amount to a pretty large sum in a year.

I therefore think that you would deserve the thanks of artists by giving them a method of managing their toning baths, by which they would use all the gold a tube contains. By enabling them to find out where an honest article is sold, you would earn the thanks of those makers of chloride of gold, who will give honest weight, by putting an end to a dishonest practice of forcing the trade by spoiling prices, and adulterating so costly an article; besides, the dealers would soon have to look a little for an honest article in buying, instead of buying only what is offered at the cheapest price.—I remain, Sir, yours truly,

AUGUST BUSCH.

London, October 23, 1863.

[Without a careful analysis, the photographer cannot obtain absolute certainty as to the freedom from adulteration of his chloride of gold. He may form some judgment by its appearance, the pure salt generally being of an orange tint, crystalline, and readily deliquescent. Adulterated samples are generally lighter in colour, dryer, and less crystalline, tending rather to granulation. A practised printer, using a good toning process, will find by the quantity of prints toned, if there be a serious deficiency of the precious metal in the salt, which professes to be its chloride; but the desultory operations of amateurs and those doing little printing, do not enable them to form an accurate opinion in this way. Those who use much carbonate of soda in the bath generally lose a great deal of gold, as the toning bath becomes inert long before it is exhausted. Probably the apparatus for facilitating volumetric analysis, which Mr. F. W. Hart is just introducing, may enable photographers readily to estimate the real amount of gold.—Ed.]

PERAMBULATOR TENT.

DEAR SIR,—While down at the island, with the camera, I have seen a contrivance which I thought of some time ago, well carried out, viz., a portable tent to carry everything *in se ipso*; and I thought it might be as useful to some of your readers as it has proved to be to myself. It consists, primarily, of a large deal box, with lid, about 3 feet by 2 by 1½ deep, mounted on 3 wheels, à la perambulator. Four slim iron rods are inserted (screwed) into the four corners of the lid, and on the top of them four others are secured horizontally, so as to form a frame like a four-post bed, to which the drapery hanging down to the bottom of the box enhance the similitude. The cover is fastened round the box by means of a strap in a groove. The yellow window is in one surface of the cover, and a bag-shaped aperture, with a string to keep it round the waist of the operator, in the other. The bath, if large, goes into an aperture of the lid. The whole forms a very handy dark room, and the box carries everything, including a small *oil-can* for water. I borrowed this machine, and have got some very good negatives—some instantaneous. *In re* lenses, I have had the opportunity of comparing as to rapidity, three varieties, with this result: Dallmeyer's No. 1 B, quickest; my own Dallmeyer's stereo (double), next; another English maker, last; a half-plate Jamini, nowhere.

I took a fully done negative of a house with foliage, the other day, in three seconds with my No. 1 triple; is that up to par? With thanks for past favours, yours very gratefully,

Ile of Wight.

G. A. BEECROFT.

Talk in the Studio.

PHOTOGRAPHIC SOCIETY.—The first meeting of the winter session will be held on the evening of Tuesday next. A communication will be read from Mr. Sutton, "On Rapid Dry Plates," and a paper by Mr. Smith, of South Kensington Museum, "On the Photographs of the Last Century."

ROYAL PORTRAITS.—Mr. Wilson, of Aberdeen, recently had the honour of a summons to Balmoral, and there secured several portraits of Her Majesty and of several members of the Royal Family.

PHOTOGRAPHIC PROPERTIES OF THALLIUM.—Mr. Crookes has recently discovered some curious photographic properties of thallium, of which we shall shortly publish particulars.

MR. STUART'S IMPROVEMENTS IN THE SOLAR CAMERA.—We have received from Mr. Stuart, of Glasgow, a model of his improved apparatus for working the solar camera without a mirror, and the description of its working read before the Glasgow Photographic Society, which will appear in our next.

GLASGOW ART UNION PHOTOGRAPHS.—Mr. Anuan has just completed a very beautiful series of photographs of drawings, by Noel Paton, for distribution to the subscribers to the Glasgow Art Union. We shall notice them in detail in our next.

FRAUDULENT CHLORIDE OF GOLD.—At a meeting of the recently founded British Pharmaceutical Conference, Mr. Reynolds called attention to several glaring cases of adulteration, one of which had reference to chloride of gold. Referring to a former paper on the subject (see *PHOTOGRAPHIC NEWS*, p. 23. vol. v.), he said that such frauds continued. The tube exhibited had contained such a salt. It was about three and a half inches long, was wrapped in green paper, and had a red label, "Chloride of Gold, 15 grains." The actual weight of the contents was 14.05 grains, but it only yielded 5.1 grains of pure gold instead of 7 grains, which it ought to have done. He had again examined some made by a firm who guaranteed 7 grains of gold in the bottle, and found precisely that amount. He had been confirmed in the belief that "honesty is the best policy," by what this firm had told him, viz., that when they adopted the principle of a guarantee, their sale for the article multiplied by ten in a very short time.

SELF-ACTING WASHING PAN.—Messrs. Bull Brothers have recently introduced an automatic washing apparatus, intended to secure the most perfect washing of prints at the least cost of water, time, or superintendence. It consists primarily of a zinc trough, with a second bottom of perforated zinc, resting about an inch from the bottom of the outer vessel, to prevent the prints ever resting in the lowest, and, consequently, most saturated with hypo, stratum of the water. The supply pipe is so curved and flattened at the aperture that the stream of water comes in with sufficient force and in the right direction to give to the prints a continued rotary motion. A self-acting syphon, the tube of which is of larger diameter than the supply tube, is attached, and comes into action as soon as the trough is full. By this means the trough is completely emptied at given intervals of, say, ten minutes or a quarter of an hour. This done, the action of the syphon ceases, the trough again fills, all the time whirling round the prints and keeping them in constant agitation; again empties, and again fills, and so on as long as the supply of water continues. It must be obvious that a much more thorough washing is thus effected in three or four hours than by six times as long soaking in still water, with slow changes. The whole affair is neatly fitted up, and, we believe, moderate in price.

ROMANTIC MARRIAGE.—PHOTOGRAPHY MADE USEFUL.—We find the following in a provincial paper published ayont the Tweed.—"A young lady correspondent favours us with a communication which we find to be quite true, and which proves beyond question the fact of the old adage that 'truth is stranger than fiction.' The narrative is too long to insert *in extenso*, but we may give the following summary without mentioning names. It would appear that a gentleman in the ancient metropolis 'The kingdom' had a friend residing in the capital of the dominions of the Grand Turk, and to this friend he some time ago forwarded a few *cartes de visites* of mutual acquaintance and relations. Among other likenesses thus forwarded was one of a good-looking young lady of about eighteen. We can easily conceive how desirous all the acquaintances of the fortunate possessor of the Scottish *cartes* became to inspect them, and the numerous criticisms expended on the collection. One gentleman friend, however, said little but thought much, and the result of his cogitations was the falling over head and ears in love with the portrait of the young lady of eighteen. What was to be done? He could not rest; he could not sleep; he must secure her for a wife; and, most certainly, he concluded if he did not hurry she would be lost to him. She looked so pretty. He quickly made his arrangements; and although he did not swim the Bosphorus like Leander of old, he quickly

engaged a passage in the first steamer and turned his face homewards. Arrived in the country of his nativity, he quickly found his way to a celebrated city in the 'Kingdom of Fife,' where the young lady dwelt with an uncle, and lost no time in calling. The young lady was absent at a 'cookie shine,' but on declaring the object of his visit, and making a proposal in duo form, the young lady was sent for, and speedily met her unknown lover. Notwithstanding the extreme ardency of his affection, he gracefully allowed her two hours to consider of the matter, at the end of which lengthened period she condescended graciously to consent to his proposal; and the marriage, we are informed, will be celebrated. Hooray! Hooray!"

VALUE OF A BROMIDE.—From a paper read at the British Association, by Dr. Gibb, on the physiological effects of bromide of ammonia, it appears that it aids in producing soft tempers as well as soft negatives. Its properties were thus summed up:—1. In small doses, more or less continued, bromide of ammonium acts as a tonic and absorbent, and exerts its peculiar properties upon the skin and the mucous membrane. 2. It diminishes the weight of the body, causing the absorption of fat, when continued with a regulated diet. 3. It improves the intellectual powers, increases the bodily capacity, and promotes healthy function. 4. Locally it possessed a soothing influence on the mucous membrane, and according to the strength and mode of its application, so does it diminish the sensibility. 5. In large frequently repeated doses, or given at intervals, it influences the entire mucous tract, affects all the special senses, and produces impaired sensibility of the various mucous outlets. 6. All the poisonous effects are produced by very large doses, as from the bromide of potassium, but in smaller doses it is more certain and reliable, causes no diarrhoea or diuresis, nor anaphrodisiasis, and its special properties are exerted sooner and with less inconvenience. The President said if Dr. Gibb's researches resulted in the discovery of something to improve the temper, it would be very important. If he knew that Dr. Gibb's conclusions were well worked out, he would not go without this bromide for the improvement of the temper. (Laughter.)

CHEMICAL DANGERS.—M. Rouelle, an eminent chemist, was not the most cautious of operators. One day, while performing some experiments, he observed to his auditors, "Gentlemen, you see this cauldron upon the brasier; well, if I were to cease stirring a single moment, an explosion would ensue which would blow us all in the air." The company had scarcely time to reflect upon this comfortable piece of intelligence before he did forget to stir it, and his prediction was accomplished. The explosion took place with a horrible crash: all the windows of the laboratory were smashed to pieces, and two hundred auditors whirled away into the garden. Fortunately none received any very serious injury, the greatest violence of the explosion having been in the direction of the chimney. The demonstrator escaped without further injury than the loss of his wig.

[ADVERTISEMENT.]

CHAPPUIS'S PATENT REFLECTORS, for photographic purposes. These reflectors, generally used in dark warehouses, ships, apartments, &c., are now applied to photography.—P. E. Chappuis, patenteo and photographer, 69, Fleet-street.

To Correspondents.

A BEGINNER.—If you are working in the field it is sometimes a great saving to put the plates away without fixing or intensifying. They may then be fixed and intensified at leisure. It is better in such case to fix before intensifying, and for that purpose perhaps cyanide is best, as being more easily removed from the film, although we rarely counsel its use. After fixing and well washing, apply a dilute solution of iodine and iodide of potassium, wash and intensify with iron and silver, or pyro and silver.

LINCOLN GREEN.—We cannot say with certainty how many times a good negative may be enlarged without offensive loss of definition. We have seen an enlargement of six diameters very good. 2. The No. 1 triple will probably answer as well as No. 2, and be more convenient to use. 3. The best advice we can give you is to read all that has appeared in our pages on the subject, and then practice until you get good results. If you prefer to have lessons, doubtless some of those who have given attention to the subject will teach you for a proper consideration.

J. FRANCIS.—There is no reason why on a fine day in the present month you should give anything like 85 seconds exposure for a portrait in the open air. Of course we cannot speak with certainty without knowing more of the conditions; but we obtained in London a good negative in about 15 seconds with a No. 1 B lens and half-inch stop, on a dry plate. The only course you can pursue, if you have no idea of the cause, is to proceed systematically; clean your lenses; try a fresh sample of collodion; try a new bath; try a fresh developer. Be assured, in any case, that the exposure you name is much too long from some cause.

J. MARTIN.—If you are satisfied that it is your sample of hyposulphite which causes the blistering, you had better abandon it, or have it exchanged, as it is probably adulterated. Bear in mind, however, that some samples of paper are very apt to blister when in the hypo. 2. Where extreme rapidity is important, you may work your No. 2 B without any stop, and get very good results; but where the light will permit, it will be desirable to use the No. 1 or 2 stop generally. Much, however, depends on the subject.

MELLIS.—We have never met with such a stain on a tannin and honey plate as that of which you send a sample, and we cannot speak with certainty of the cause. Primarily, it is probable that imperfect washing is the cause, some free nitrate having been left in the film when the tannin and honey was applied. Do you add a little acetic acid to the first washing water, as Mr. England recommended? Such a method is very favourable to cleanliness.

R. J. SPROAT.—We shall be glad to hear details of your process.

J. A. V.—The first are good, but not so good as the second. In our estimation, there is about the same difference in quality as in price.

HOBERTON.—We cannot speak with certainty, as we have not tried the lenses in question. It is probable that they are French, and will cover as well as such lenses generally do, being, probably, carefully selected by the dealer.

G. H.—In the London Photographic Society, if you join at the half-year, you only pay half a year's subscription. If you join at the forthcoming meeting, on the 3rd of November, you will pay half a year's subscription, besides the entrance fee, of course. Joining now will qualify you for exhibiting at the next Exhibition. 2. The time for sending in specimens will be duly announced. 3. The manager of our advertising department will communicate with you as to the price of an advertisement.

D. S. STURRO. has tried the addition of nitrate of soda to his printing bath, and signally failed. He wishes to know how the process can have succeeded in other hands, and failed so completely in his own? We are as much in the dark as he is; but it is clear the fault is in his manipulation, as we have seen many excellent results by the method obtained by others. Further, his bath contained 35 grains of nitrate of silver, he states, in addition to the nitrate of soda, and such a strength of silver ought to have guaranteed him against entire failure, even if the nitrate of soda exercise no influence whatever. The prints enclosed are mottled, marbled in a singular manner, as if portions of the paper had never come into contact with silver at all. Agitate your solution to mix it properly, and try again.

G. W. O. says that he has tried Hollis's Opal Mucilage and abandoned it, because it was manifestly acid, turning blue litmus paper of a bright scarlet colour. If this be the case, we should hesitate to use it. Our own sample was not acid, and we were assured it kept without any injury. We shall try it further.

AN OPERATOR.—The stain on the print you enclosed was due to some trace of hypo from dirty fingers, or some other cause, coming into contact with the print before fixing. 2. All the collodions you mention are good: we should prefer 3, 1, or 4.

C. W. L. F.—The use of a toning-bath of gold and lime, good negatives, and deep printing and toning, will give you perfect blacks. See some of the recent articles on lime toning.

D. C.—In order to copy an object the same size, you must draw out the body of your camera until the focussing-glass is the same distance from the lens as the lens is from the object. With a good lens, which will probably have about 6 inches equivalent focus, the distance will be about 12 inches. Place the picture to be copied in a good light, and the camera quite parallel at a distance of about 12 inches. Now draw out the body of your camera 12 inches, and cover over the space between the front and back with black velvet or cloth so as to make it light, and so improvise a long camera. By a little adjustment you will then get a sharp image the size of the original. Proceed then to take a negative in the usual way. You should procure a good manual giving information on these points. You will find Hughes's an excellent one.

HENRY PIPPETT.—Some samples of paper are more apt to lose tone in the hypo than others. When you meet with such a sample, tone much deeper than you would otherwise do.

B. B.—Your 2 B lens will cover about a half-plate, properly stopped down for landscapes. The front lens of the combination may be removed, screwed into the place of the back lens, which must be removed altogether; you will then have a landscape lens, producing pictures about 10 by 8, or thereabouts, the exact size we cannot state.

MEALIS.—We will write shortly.

J. H. UNDERWOOD.—We will return to the subject shortly.

W. ABERDEEN.—The required information in our next. Several Correspondents in our next.

GLASGOW ART UNION PHOTOGRAPHS.

WE have considerable satisfaction in recording the fact, that the experiment tried last year by the Glasgow Art Union, of substituting the distribution of photographs amongst the subscribers instead of engravings, as heretofore, has been so successful and satisfactory as to induce the Committee of Management to make a similar distribution this year, and there is every reason to hope that the plan will not be discontinued, as we find the Lord Provost remarking at the annual meeting, that it was a great improvement on the old system, and gave great satisfaction to the subscribers. We are glad to record this, as we cannot forget that certain art authorities proclaimed last year, that such a step was merely the death-throe of an already moribund body, and that immediate dissolution must follow. We have reason to believe, however, that it was really the first step out of serious difficulties, and that it will lead to continued and increased prosperity.

The presentation photographs of last year, as many of our readers remember, consisted of copies of three original paintings amongst the chief prizes. This year we have a series of five paintings illustrating a special subject. It is entitled, "Bond and Free: Five sketches illustrative of Slavery, by J. Noel Paton, R. S. A." The photographs are by Mr. Thos. Annan, whose magnificent rendering of last year's pictures gave such satisfaction. It has been suggested that the selection of a party subject, the partial occasion at the present moment of one of the most terrible wars which ever disgraced the annals of the world, is open to some question. This is unquestionably to some extent true; but we apprehend that the treatment here is sufficiently broad to obtain almost universal sympathy; it simply offers an indignant protest against any child of man, however low in organization or degraded in habit, being held as the chattel of his fellow man; and there are few, however divided opinions may be as to the proper time and mode of ending this enormity, who do not agree in this protest. Be this as it may, however, the series of pictures is one which will command a wide circle of admirers.

The first picture of the series is entitled *Verbum Dei*. It is a figure of Christ, and grouped around his feet, some in passionate entreaty and some in despairing anguish, men, women, and children, bearing the badge of slavery. The simple majesty of the figure, one hand resting on the head of a kneeling figure from which grief seems to have exhausted all the tears, the other extended as in warning, is marvellously grand. The face is no longer expressive of gentleness and love only, but bespeaks the terrible-ness of the denunciation he is uttering, "Whoso shall offend one of these little ones which believe in me, it were better for him that a millstone were hanged about his neck, and that he were drowned in the depth of the sea." The excellent grouping, the fine chiaroscuro, and the severe excellence of the drawing, as well as the perfect rendering of the sentiment, constitute this a grand picture. The second of the series is

entitled *The Sale*: although a forcible picture, well drawn, and well grouped, it has a little of the clap-trap and exaggerated element in it. The sale is supposed to take place in the open street and within sight of the capitol at Washington; such a position, not true, and scarcely possible, is doubtless chosen with the painter's licence to give additional point to the horror. The prominent event, too, amid the many minor sad features of such a scene, is perhaps the most revolting ever associated therewith. A beautiful young girl, nearly white, is in the hands of the auctioneer; her dress, which suggests that she has been gently reared, is partially removed to show the faultless modelling of the bust and arms, whilst the luxuriant locks of waving hair are drawn through the auctioneer's fingers to display them to advantage. The poor girl hides her face in her hands, in speechless shame and agony. Some of the buyers look on with stolid indifference; it is so much business in course of transaction; others, with gloating salacious leer; there are partings, too, going forward, "such as press the life from out young hearts." The picture is altogether very fine and forcible, but almost unnecessarily painful. The next picture is not less painful: but here to depict the scene at all, it must be painful. It is entitled *The Capture*. Fugitive slaves, a father, mother, and child, have fled into the jungle, where they have been hunted down by bloodhounds, canine and human. The father has just been shot down, and the savages in pursuit are making their final dash in to secure the others; the mother stretches her arm with futile eagerness in front of her murdered husband, clasping close her babe with the other arm. A bloodhound has already, however, sprung at her, and men armed with rifles and revolvers are closing round. This picture is characterized by the same forcible and severe drawing as the others. The fourth picture in the series is one we like best, not merely for the sake of the subject, but for its admirable treatment, and exquisitely fine chiaroscuro. It is entitled, *The Rescue*. It represents the hold of a slave ship, with its living cargo packed and huddled together in their floating prison. The hatchway has just been removed, and eager faces full of honest manhood and good nature—British tars and British officers—are looking down, and strong arms are stretched forth to aid the poor fainting wretches to come forth into the blessed light of heaven that streams joyously down to carry hope into the dark prison. The varied expressions of hope, doubt, and of the "helpless, hopeless brokenness of heart" which is beyond hope, are wonderfully rendered, and as a study of light and shade, the picture is admirable. The last picture of the series is entitled *Freedom*. Well drawn, and in many respects a good picture, we like it least of all. It lacks variety of idea. The happiness of freedom seems rather dreary. The idea of freedom is chiefly rendered by groups of persons reading or being read to. The capacity to read and enjoy reading is surely one of the greatest gifts of God to man; but in a picture like this we should like some variety in the symbolical rendering; we should like to see the flourishing of the arts of utility and beauty; we should like to see the enjoyment of healthful

and innocent sports, and a variety of phases of enjoyment, besides reading good books and looking demure. With all the drawbacks to individual pictures, however, the series is a grand one; the art is very true, and has a noble aim.

Coming to Mr. Annan's share of the work, it is unexceptionable, and confirms his position as one of our very first masters of photographic reproduction. And here we have an interesting fact to record regarding the method adopted to secure the best results. The original sketches were drawn by Mr. Paton, the same size as they are now published, which is about nine inches by seven inches. Of these Mr. Annan made enlarged copies, about twice the size of the originals. Upon prints from these enlarged negatives Mr. Paton now made the corrections, which the enlargement of the drawings or the short-comings of photography showed to be necessary. It will readily be seen that the artist thus having an opportunity of touching upon his work would be able to supply many deficiencies, and add many skilful touches upon which the beauty of the finished result would largely depend. From these re-touched large prints, fresh negatives were made of the original size, and we have the result in prints admirably full of tone and gradation.

The great success of photography as a means of translating the works of the painter scarcely needs, in the present day, to be affirmed; it has come to be a largely-accepted fact. It is, however, satisfactory to be able to add the opinion of a gentleman of such high artistic eminence as Mr. Noel Paton in testimony of the fact. In a letter to the Secretary of the Art Union, he says, in regard to the last series:—"As photographs, they are certainly extremely successful. . . . Assuredly a photograph may be so managed as to convey with a fidelity, attained by but few engravings, the more subtle, valuable and least easily reproduced qualities for a work of Art; and I hope ere long to see the technical difficulties which at present, to a great extent, obstruct the application of photography to the reproduction of pictures entirely overcome. If the efforts of the Glasgow Art Union assist, as I have no doubt they will, in the accomplishment of a result so much to be desired, they will merit the thanks of all true lovers of Art." The method adopted this year by Mr. Paton's co-operation, which we have just described, will doubtless largely overcome any technical difficulties which may stand in the way of perfect success.

Of Mr. Annan's method of working there is nothing new to tell, as a source of success. He uses a bromo-iodized collodion, iron development, and triple achromatic lens. The secret of his success however lies in one sentence; he says, "My aim is never to be satisfied with anything, so long as I know it can be done better." We commend this mode of working to the beginners amongst our readers.

Scientific Gossip.

NEW PROCESS FOR SILVERING GLASS.—ALKALINE DEVELOPING AGENTS.—MODIFIED DAGUERRETYPE PROCESS.

PROBABLY, part of the reason why the old Daguerreotype process has fallen into disuse, is owing to the expense of the silvered plate, and the immense amount of trouble required in cleaning it for subsequent operations. Could these drawbacks have been easily overcome, there is little doubt that this process would have successfully held its ground, even against collodion; for, notwithstanding the perfection to which modern photographic processes have been brought, they can scarcely yet equal in delicacy, half-tone and softness a good Daguerreotype. Since Daguerreotypes have gone out of use, several methods have been devised for giving other substances besides copper a very perfect coating of silver. Thus we know many ways of precipitating a surface of absolutely pure silver on to glass in such a state that it will assume, with a little polishing, a surface more perfectly brilliant than could be obtained on a common Daguerreo-

type plate without a tedious amount of trouble; the silver, moreover, thus precipitated on the glass by chemical means, has the great advantage over the old plated copper in being absolutely pure—so pure, in fact, that silver so prepared has been used by M. Stas in his researches upon the atomic weight of this metal.

Among the many processes for silvering glass, that devised by Mr. Drayton is considered the best. The recent employment of silvered glass for the reflectors of telescopes having caused great attention to be directed to this subject, many endeavours have been made to simplify the somewhat complicated operations. A process has just been published by Mr. Martin, which, from the firm adherence of the layer of deposited silver, and the simplicity of the different steps of the operation, seems to fulfil all the conditions necessary for rendering the method of general use. The solutions are four in number, they require some care in their first preparation, but once made they are always ready, and can be used with great rapidity and certainty for depositing a lustrous, mirror-like surface of silver on a piece of glass of any desired shape or curvature.

Solution 1 is prepared by dissolving one part, by weight, of nitrate of silver in ten parts of distilled water.

Solution 2 consists of an aqueous solution of pure ammonia, having a density of 13° Cartier.

Solution 3 consists of four parts of pure caustic soda in 100 of distilled water.

Solution 4 is made by dissolving 12½ parts of the best white loaf sugar in 100 parts of distilled water. To this add 1 part, by measure, of nitric acid, boil for twenty minutes, in order to alter the molecular arrangement of the particles of the sugar, and then add water to increase the volume to 500 parts by measure, and finally add 50 parts of alcohol.

These solutions will remain unchanged for a long time. When required for use, prepare an argentiferous liquid by pouring into a flask 12 parts, by measure, of the silver solution, No. 1; 8 parts, by measure, of the ammoniacal solution, No. 2; then 20 parts of the soda solution, No. 3; and, lastly, add 60 parts of distilled water, in order to make up the volume to 100.

If the proportions have been properly observed, the liquid so prepared will be perfectly clear, but will be rendered turbid by the smallest addition of nitrate of silver solution. It must be allowed to remain without disturbance for twenty-four hours to permit the floating particles to settle. The clear liquid decanted from the sediment will then be ready for use.

The surface of glass which has to be silvered must be well cleaned with a tuft of cotton and a few drops of nitric acid, and then washed with distilled water. Drain it, and support it on the surface of the silvering bath, which is composed of the above-described argentiferous liquid, with the addition of 1-10th or 1-12th by volume of the sugar solution, No. 4. The surface to be silvered should, by preference, be at the upper part of the liquid, so that the silver may be deposited on it from below upwards. There are two advantages in this—1, the deposit is finer and more even; and, 2, there is no danger of floating particles of dust settling on the surface. It is, however, scarcely necessary to say that silver will be deposited upon every part of the glass which is under the surface of the liquid, as well as upon the sides and bottom of the vessel, so that, as a matter of economy, as little as possible of the back of the glass should be exposed to the action of the liquid. The action seems to be somewhat of a photogenic character, being more rapid in the light than in darkness. Under the influence of diffused light the liquid becomes yellow, then brown, and in a few minutes the whole of the exposed surface of the glass will be covered with a fine deposit of silver. In about a quarter of an hour the thickness of the metallic coating will be sufficient to bear the subsequent operations without injury; it must then be washed with plenty of water, and rested by one corner on several thicknesses of blotting paper to dry spontaneously. The surface will now be covered

with a thin whitish veil, which may be readily removed by gentle friction with chamois leather; it may afterwards be polished with jewellers' rouge, when a perfectly brilliant surface will be produced.

We are aware that some experiments have been tried on the application of similarly silvered glass plates to photographic purposes, but they have certainly not been followed up with as much perseverance as so promising a line of research deserves. Not only may the ordinary operations of the Daguerreotype process be performed upon such a surface with far more chance of success than when a clumsily rolled silver-copper plate was the basis of the photographer's manipulations, but we have little doubt that a somewhat similar process to the one in present use, or a modification of that and the Daguerreotype, could be worked out without an incommensurate expenditure of time and trouble. The surface of silver is readily converted into iodide by exposure to the vapours of iodine, and the compound thus produced could be treated as a prepared Daguerreotype; the silver could also be converted into iodide of silver, by being washed over with an alcoholic solution of iodine, or an aqueous solution of that element in iodide of potassium. The iodide of silver prepared thus in the moist way would, no doubt, have similar properties to that prepared by double decomposition in the collodion process, and, like it, could be rendered sensitive by a bath of nitrate of silver, and, after exposure, developed by any of the ordinary developing agents. It would also be interesting to try whether a combination of the two processes would not give good, and, perhaps, novel results; thus the silver could, in the first place, be iodized in the dry way, the subsequent operations being performed as in the wet process.

It would also be interesting to see whether the silvering solution used to deposit the precious metal on the glass surface would not constitute an excellent developing solution, both in this suggested process and in the ordinary collodion process. The action is certainly more energetic under the influence of light; and, as a general rule, it may be stated that the action of visible radiant light in inducing chemical change is similar in its effects to the continuing action in the dark which radiant light induces in compounds of silver with iodine, and other members of that family. The silver would, we have little doubt, be deposited by the liquid only upon those parts of the sensitive surface where the equilibrium had been previously disturbed. Most of the developing agents in common use would act in darkness after the lapse of some little time, without any action being previously set up by light, and in this respect the resemblance between the solutions is complete. The deposited silver would most probably retain the same character as when originally precipitated on the glass, and the developed image, viewed as a positive, would have the peculiar brilliant appearance which was formerly so much admired. We should think that such a solution, alkaline in its character, would be especially useful in some of the dry processes, where the development, proceeding more leisurely, the molecules of silver would have time to arrange themselves on the plate in the manner most agreeable to themselves, and therefore more likely to stand any subsequent friction which would be necessary to obtain a good polish.

ON THE BEHAVIOUR OF CHLORIDE, BROMIDE, AND IODIDE OF SILVER IN THE LIGHT, AND ON THE THEORY OF PHOTOGRAPHY.*

BY HERMANN VOGEL.†

α. Experiments with pure Chloride, Bromide, and Iodide of Silver.

CHLORIDE of silver was prepared under a dull gaslight by precipitating nitrate of silver with an excess of pure chloride of sodium. It formed the well-known caseous mass, and was easily

filtered and washed. The washing was continued until the water gave no reaction of chlorine. Bromide and iodide of silver were prepared in like manner by precipitating nitrate of silver with an excess of bromide and iodide of potassium. Both were thrown down at first in a caseous form, but afterwards, as the precipitant was added in excess, formed a fine powder, which was very slowly deposited, ran partly through the filter, and stopped its pores.

The chloride thus obtained appeared white, the bromide pale yellow, and the iodide straw yellow. They were all dried, after careful washing, and kept in the dark.

To test their behaviour towards light, they were divided into small portions in test-tubes by lamp-light, and broken up with a glass rod; the test-tubes were then closed with a cork, or sealed up, and exposed to the light. In this way a number of tubes were filled with the three salts, and simultaneously brought into the light. In a short time a change of colour was observed in the chloride and bromide. The chloride became violet, the bromide grey. These colours increased in intensity with time, but in a few days attained a maximum. The chloride then appeared brownish violet; the bromide *impure pale greyish violet*. This colour was only superficial; the centre of the samples remained white.

The iodide of silver, prepared as above, did, on the contrary, not undergo the least change of colour, even by exposure for months to an *intense* light.

In most chemical text-books it is stated that chloride and bromide of silver "*bleichen*" in the light. This is incorrect. Even by exposure to the light *for years* pure chloride and bromide of silver undergo no blackening, they become coloured only as above described.

Seebeck, moreover, states (Poggendorff's *Annalen*, ix. p. 172) that the blackening of chloride of silver takes place only in the presence of moisture. This also is incorrect. Chloride of silver when perfectly dry, or even fused, acquires a violet colour when exposed in a sealed tube.* This change of colour is accompanied by a *chemical* change, which is manifested by chlorine and bromine being set free. I ascertained both—

α, by the odour, which was also observed in the case of the chloride by Scheele, Wetzlar, Wittstein, Hunt, and others; and

β, by the reaction with iodized starch-paper.

I exposed simultaneously to the light of the sun a tube with chloride and another with bromide of silver, having strips of iodized starch-paper fixed in their corks. The chloride of silver soon became pale violet, the bromide grey. Within a few minutes the end of the paper nearest to the bromide of silver acquired a faint blue colour; in the case of the chloride, distinct coloration did not make its appearance until the lapse of a quarter of an hour. In half an hour the strip of paper with the bromide was intensely blue; subsequently its lower extremity became yellow, certainly in consequence of the formation of bromides of iodine and starch. The strip of paper with chloride of silver was coloured more slowly. The experiment was repeated with the diffused light of the blue sky, and gave the same result. The paper with the bromide of silver became more rapidly and deeply blue than that with the chloride. The same experiment was made with fused chloride and bromide of silver. These were exposed in sealed tubes for several days, and, on opening them, a strip of the starch-paper was introduced. This was but slightly coloured by the chloride of silver but much more distinctly by the bromide. From these experiments it is evident that chloride and bromide of silver are decomposed with evolution of chlorine and bromine by exposure to the light, and that this takes place *more* rapidly with the bromide than with the chloride.

We have now to consider the question as to what compound remains after the exposure of chloride and bromide of silver. As we have only pure chloride and bromide of silver to deal with, and the experiments just described prove the evolution of chlorine and bromine, the following cases only are possible:—

1. Ag Cl and Ag Br are decomposed into their constituents—silver and free chlorine or bromine;
2. There is a production of a subchloride and subbromide and of free chlorine and bromine.

* We have a sample of dry chloride of silver which has been exposed to light in a stoppered bottle for nearly four years without any change. The sample was prepared and given to us by Dr. Alfred Taylor, of Guy's, and was prepared by the action of chlorine upon silver foil. There is not, we believe any free chlorine.—ED. P. N.

* Continued from p. 5-3.

† Poggendorff's "*Annalen*."

No third case is conceivable.

If the first decomposition be the true one, free silver must be present in the masses of chloride and bromide of silver affected by light. To ascertain this, I boiled chloride and bromide of silver which had been exposed for months to the light with pure nitric acid of spec. grav. 1.2. I then allowed the chloride and bromide to settle completely, drew off the clear fluids with a small pipette and tested them for free silver, by carefully floating upon them very dilute muriatic acid. The smallest trace of free silver is thus betrayed by a white cloud. *No such trace could be discovered in my frequently repeated experiments either with chloride or bromide of silver.* This indifference towards nitric acid was also manifested by the very small change of colour which the chloride and bromide underwent when boiled with nitric acid. Even when exposed chloride and bromide of silver were left standing for months with nitric acid not a trace of silver was dissolved. From this we are justified in assuming that, during the exposure of chloride and bromide of silver to the light, a subchloride or subbromide is formed—an opinion which has already been expressed with regard to the chloride by A. Vogel, Wetzlar, Wittstein, and others.

Guthrie's objection that the silver occurs in the passive state, that is to say, insoluble in nitric acid, is scarcely worth refutation. A passive state is the consequence of a coat of oxide or chloride which is formed upon the metal. But how can we assume the formation of a chloride, if we at the same time assert that this is decomposed by the light?

Hurst's assertion that oxide of silver is formed, is likewise invalidated by my experiments; for in this case it must be dissolved by the nitric acid, and thus manifest a silver reaction. Spiller's assertions are too hypothetical in their nature; he expresses opinions only half supported by facts.

Dawson's experiments (*vide supra*), are of more importance. He found that chloride of silver, after exposure to the light with solution of free silver or of chloride of sodium, contained free silver. This fact, however, is by no means surprising; for solution of nitrate of silver is slowly decomposed by the light of the sun, and deposits black spangles of metallic silver, as I have found by experiment; hence chloride of silver exposed with a solution of free silver, must contain free silver. But even the presence of free silver in chloride exposed with an excess of chloride of sodium, need not astonish us; for the latter is able to decompose Ag^2Cl , with separation of Ag, as was discovered by Wetzlar (*loc. cit.*). Maloué's views prove nothing against my theory; for the assertion that the brown fluids obtained by him by mixing a solution of phosphoric ether with one of silver contain metallic silver is not proved, and I might call attention to the fact that the solution of Wöhler's protocitrate of silver is likewise of a brown colour.

It is certainly impossible to determine the quantitative composition of the subchloride formed by the action of light, as only the outermost stratum of the salts in question is affected by exposure, and this cannot be separated from the subjacent, unaltered chloride and bromide.

On the other hand the qualitative reactions are of importance. If ammonia be poured over chloride of silver deeply coloured by exposure, the greater part of the latter is dissolved, and grey granules remain. By pressure with a glass rod these become silver-white and of metallic lustre; and as they dissolve readily when heated in ammonia, they are metallic silver.

This reaction, which induced Scheele to assume the presence of metallic silver in chloride of silver after exposure to light, is presented also by the pure subchloride, as prepared by Wetzlar and Wöhler. The former obtained it of a black colour by the action of perchloride of iron upon silver leaf (*loc. cit.*); Wöhler procured it of a brown colour by precipitating a solution of protocitrate of silver with hydrochloric acid (Poggendorff's Annalen, xvi. p. 629.) This body also yields no silver to nitric acid (Wetzlar), and is decomposed by ammonia, chloride of silver being dissolved and silver remaining (Wetzlar and Wöhler). Its indifference towards nitric acid proves that this body cannot be regarded as a mixture of chloride and metal.

All doubt as to Ag^2Cl being contained in chloride of silver coloured by exposure to the light must, however, disappear, if we can obtain by other means, from compounds undoubtedly containing protoxide of silver, mixtures of subchloride and chloride silver similar to those produced by light. In this I succeeded by the agency of Rose's compound of protoperoxide of iron with protoxide of silver, obtained by pouring sulphate of iron into an ammoniacal solution of silver (Poggendorff's Annalen, ci. p. 321.) When hydrochloric acid is poured over this compound,

the oxides of iron are dissolved, and there remains a violet powder, which, both in its colour and its behaviour towards nitric acid and ammonia, precisely resembles chloride of silver coloured by exposure to light.*

I succeeded yet another way in preparing a similar violet colour, chloride of silver. I found (Poggendorff's Annalen, cxvii. p. 316,) that my crystallized peroxide of silver, which, when fresh, appears pale violet colour, when exposed to the light, very soon becomes black, with evolution of oxygen, at the same time losing its lustre. The black body dissolves in dilute nitric acid, and in ammonia, leaving a residue of black, granularly pulverulent, metallic silver, which, when pressed with a glass rod, becomes silvery white and shining. That this silver does not pre-exist in the black body, appears from the fact that it cannot be detected by pressure with a glass rod. The oxide of silver altered by exposure to light, consequently consists of a mixture of Ag^2O and AgO , and the former, when treated with acids or ammonia, furnishes granularly pulverulent silver, exactly like Wöhler's protoxide of silver. This oxide of silver, blackened by the light, gives with hydrochloric acid a body precisely similar to chloride of silver coloured by light, both as regards colour and behaviour to acids and ammonia.

I likewise found that carbonate of silver exposed to the light furnishes a body which produces with hydrochloric acid a chloride of silver containing subchloride; and, judging from this, it seems extremely probable that all silver-salts which are reducible by light are reduced first of all to the state of protoxide, or of a haloid salt analogous thereto, and that, in all cases in which metallic silver has been at the same time detected, this is a secondary product resulting from the decomposition of the protoxide of silver formed by the action of light.

Just as I obtained a chloride of silver containing subchloride, I also produced a bromide containing subbromide, namely, by treating Rose's compound with dilute hydrobromic acid, the latter prepared by the distillation of bromide of potassium with sulphuric acid. There was produced a pale greyish-violet body, perfectly similar in appearance to the bromide of silver after exposure to light. By boiling with nitric acid it became grey, and this also was the case with exposed bromide of silver. It also yielded a trace of silver; but this certainly originated from the material used, as, after washing and further boiling, no more silver was dissolved. The mass which had been boiled with nitric acid, when treated with ammonia, acquired a darker grey colour, and a grey powder settled to the bottom. This dissolved in nitric acid, and then gave a silver reaction. The same reaction was exhibited by bromide of silver, after exposure to light. I poured ammonia over this, when a small portion was dissolved; by decantation and repeated treatment with ammonia, all the bromide of silver was at last dissolved, and there remained a few small, delicate granules, which dissolved in nitric acid, and then gave a reaction of silver.

As the removal of the whole of the bromide of silver is troublesome, and during it the small quantity of silver separated may easily be washed away, I poured ammonia over these other portions of bromide of silver which had been exposed to the light, and then washed them simply with water. The Ag^2Br formed upon the surface must evidently have been decomposed by this means, and left behind with the undissolved bromide of silver. This yielded distinctly demonstrable quantities of silver to nitric acid, whilst no trace of silver was extracted by nitric acid from the bromide of silver which was not treated with ammonia.

It is, therefore, evident that bromide of silver behaves exactly like the chloride when exposed to the light,—that by this means a body is produced which exhibits the same behaviour towards reagents as the exposed chloride, justifying the conclusion that it contains sub-bromide of silver (Ag^2Br). The sub-bromide, however, appears to offer greater resistance than the subchloride to decomposition with ammonia, which is certainly due to more difficult solubility of bromide of silver in ammonia. The silver reactions presented by chloride of silver exposed to the light and treated with ammonia, were much more intense, under otherwise similar circumstances, than those of the bromide under the same treatment, and I found this to be the case also with the bodies produced from Rose's compound with hydrochloric and hydrobromic acids.

(To be continued.)

* I must remark that I do not quite admit the composition of the black body given by Rose. I shall take another opportunity of reverting to this point.

IMPROVED SOLAR CAMERA.

BY JOHN STUART.*

I COULD have wished that some subject more interesting should have engaged your attention on this the opening night of the season. The difficulty attending a description of the solar camera, which I have just constructed, is great indeed; to understand it well, you would require to see it; but my task to-night is, by the aid of a model, photograph, and description, to bring my latest improvement on the solar camera before you. If I could have shown you a larger collection of photographs taken by it, it would no doubt have been much more interesting to you; for me to have more was quite impossible, as, since it was finished, we have had no sunshine worth speaking of. If you remember the faults which I pointed out in the old style of solar camera (with the mirror), you will then be able to understand what I have tried to avoid in the new one. Looking at the model or the photographs, you may be apt to think it rather a formidable piece of apparatus for the operating rooms of a photographer, and, doubtless, it would be to have it in his operating room; but it is not intended to be placed there, but is operating room and solar camera combined, and can be placed in the top of the house or (as in my case) in the garden, placed so that no high houses will intercept the sun's rays. I will now proceed to describe in detail (as well as possible) its form and construction. Some of you may have some difficulty to understand me from the terms requiring to be used, but after I have finished the description, I will be happy to explain to any of you, from the model or photographs, any part of it you may not have understood.

Beginning at the foundation, the first part is a frame of an octagon shape, the square of which is about 11 feet, formed of planking 9 in. broad by 3 in. thick. Bound together at the angles, by bolts running at right-angles, are two planks of same size, which intersect at the centre of the octagon, and serve to fix a centre-pin for the house to turn upon. Upon this octagon-shaped frame is fixed a circular iron rail; to the inside of the rail, and on the plank, is fixed a tooth and pinion rack, all the way round, or nearly so. Above the frame already described is another of the same shape and size, and similarly constructed, but not of such heavy timber. Upon the under side of the frame are fixed grooved wheels, which work upon the circular rail. This frame is covered with flooring, which forms the floor of the house. Sitting on the top of the flooring is a combination of tooth and pinion wheels, which works on the rackwork under, and serves to turn round the upper frame. Looking at this part, which I have described, you would almost be inclined to take it for a railway turning table. You will now please follow me, while I, step by step, build up the house upon the table, which I have just described. Referring to the model, you will see that the back part of the house stands perpendicular, the front sloping in towards

the top, the object of which you will presently understand. At the points of the octagon-shaped frame are placed posts, which run up to the height of about 14 feet, and are 5 in. by 4 in., and bound together at the top by a frame which slopes down towards the back, so as to run the rain off by the back of the house. Owing to the slope in front, the top of the house is only about 11 feet by 5; the framework is then closed in by lining nailed upon carps (in this lining there is a space left for a door, so as to give easy ingress to the house), and when fitted in between the standards, it is only screwed up, so that it may be easily removed in case such should be required. The framework and lining can all be undone in about an hour's time, and packed up in bundles. In the front space, the lining only comes up about five feet, two shutters close up the rest of the space, the one a rolling, and the other a sliding shutter. With these the space is closed up, when the camera is not in use, which keeps the place wind and water tight; the next part which I have to describe is the camera proper. It is a square frame, 15 feet long, 5 feet broad, by 3 feet 6 in. wide, with rails running through it at various intervals, so as to make it as firm as possible, and as light as is consistent with rigidity. The part of the frame which is exposed, when working (see photograph), is covered with cloth, so that the joints, though coming and going with the weather, will not admit the light. In the inside of this frame is a moveable partition of black cloth, running from top to bottom; also two frames, horizontal to this partition, which move upon sliders, to serve as focussing screens to receive the image. On the top of this camera proper are placed too small boxes, which hold the condensers, the negatives, and enlarging lenses. In the inside there are arrangements for focussing, also for a horizontal and vertical motion of negatives. All the movements have to be so arranged that they can be pinched up with screws, so that in the process of printing no further movement can take place, as the slightest motion would be fatal to a good result. The square frame, which I have just described, is then hung on its centre, or as near as possible, so as to give balance, and when so hung, moves to ascension and the declension of the sun. That this motion may be performed with ease, it is swung down on the top of sliding shutter. That shutter is raised and lowered by an endless chain, running over pulleys, and wrought by suitable machinery inside solar camera house. The camera, when attached to the shutter, is

taken up and down with it; when not in use it is detached from the camera, thrown back, and stands perpendicularly. By the means already described we have got the two motions. The great objection urged against solar cameras is the difficulty of keeping the sun shiing parallel through the condenser and enlarging lens all the time of printing. In this I find no difficulty. The way I keep the sun in the same place all the time is by having a tube fixed by the side of the camera, and running parallel with it. Through this tube the sun must shine, and it will only do so when the

* Read at the Glasgow Photographic Association, on the 23rd. ult.

camera is kept directly pointing to it; and if such is the case, the rays must strike the centre of the condenser and enlarging lens. You may ask, Well, what are the advantages to be gained for all this extra expense? In the first place, you can print the pictures in about one-half the time taken by a mirror camera. Secondly, two pictures can be done at once, one motion serving both. Thirdly, any lad with ordinary judgment can work the camera. Fourthly, the pictures obtained are much sharper; and although there are no perfect specimens to-night, I am fully persuaded, from what I have seen of the working of both machines, that the superiority of this over the reflecting camera is beyond dispute.

THE GHOST IN THE NEGATIVE.*

OBSERVE the illuminated circle on the ground glass of a camera which has been produced by certain lenses, when those lenses especially are directed so as to take in the direct rays of the sun or from a very brightly illumined cloud; you will ascertain a central part or central parts different from the rest, more hazy and indistinct, although in general exhibiting more illumination. Such lenses will produce on the negative under such circumstances the "Ghost."

It becomes our task to endeavour at least to demonstrate, what are some of the causes that produce this spectral apparition, this spirit of a picture.

In the first place, let us make an experiment.

Take a lens, as, for instance, AB in the figure, of about four inches in diameter, and whose radii of curvature are short, that is, whose magnifying power is great; and hold up the lens so as to catch the rays of the sun, and find the burning point or focus of the lens. Let OQ represent a beam of such rays, which, after refraction, will cross each other in the point C at the other side of the lens, and will produce combustion there on any combustible body. This is the burning point or the principal focus of the lens. In addition to this focus, however, such a lens has frequently two other—speaking in general terms—or secondary foci, whose position we will point out.

Whilst an assistant is holding the lens so as to produce combustion in C, or, better still, let the lens be fixed in a rigid stand capable of the proper adjustment as to direction; then, bringing your finger into the axis of the lens, and between the sun and the lens, as in the point E, you will desery another illumined point, where combustion can in like manner and cosentaneously be produced, though more feebly. It is, however, a fact: a match can be set on fire either at E or at C.

We expect, therefore, to find a picture of the sun both at E and C. The picture at E is formed by rays reflected from the concave surface AFHIGB, but especially by those peripheral rays, such as NF and RG, and others exterior to them,

* From *Humphrey's Journal*.

when they form an angle of incidence equal to or greater than $40^{\circ} 49'$, which is the limit for transmission for crown glass.

Furthermore, if the lens has not been corrected for spherical aberration, we shall have an innumerable quantity of foci for the peripheral rays along the axis from C towards T and onwards towards the vertex, until transmission is no longer possible.

Now the picture at E may be regarded as an independent sun which will produce, according as its position is nearer to the lens than the principal focus or farther off, either a virtual image on the axis towards P or beyond, or a real image as at D.

Thus, then, the central rays or the beam OQ from the sun form an image of the sun at C; the rays XH and ZI, being more external, will form a distinct focus at T, where they cross and, arriving at the ground-glass, cover the space LCM, where the image is much enlarged and indistinct.

The rays NF and RG, still more external, and making angles NFE and RGE greater than $81^{\circ} 38'$, will produce a reflected image of the sun at E, and the rays EH and EI of the pencil FEG will form another image of the sun distinctly at D, but very indistinctly and enlarged on the ground-glass on the space LCM.

It is evident then, if matters be as we say, that we shall be troubled with ghost-like apparitions on our negatives in the central parts under the following circumstances:

1. If the lens is not thoroughly corrected for spherical aberration.

2. If the radius of curvature of that surface of the lens next to the ground-glass be so small as to cause any of the external parallel or oblique rays to be reflected back, inasmuch as the incidental angle exceeds the angle of transmission.

3. If so much of the lens be left exposed as to allow the above mentioned external parallel or oblique rays to act.

4. If the lens, under the above-quoted conditions, be exposed to the direct rays of the sun.

Supposing the lens be well corrected for spherical aberration, it may still give rise to the apparition in question.

It will be seen from the above discussion that the *Ghost* on the negative is not a fortuitous phenomenon, but one which the optician has quite under his control without the intervention of holy water or any other spells of *exorcism*.

In the first place, the lens or the combination of lenses must be well corrected so as to bring all the foci of central and peripheral rays, whether parallel or oblique, upon the same flat surface or plain perpendicular to the axis of the lens. To do this, the lens will have to be cut down considerably on the edges, by which the central parts alone must be made available; or parallel rays alone be admitted, which is effected in a great measure by elongating the *obturator* in front of that surface which is exposed to the object to be copied.

Secondly, the posterior surface of the last lens, if convex, as well as of any other intermediate and independent lens, if convex, must have a convexity of such a nature as to preclude the possibility of reflections, whether by parallel or oblique rays, at angles at which transmission is impossible.

Globular lenses, corrected for spherical aberration, like Coddington's, or for spherical and chromatic aberration like Harrison's, if a large part of the spherical surface of said lens be left exposed, must of necessity be *haunted*; and the *falling flap* on the camera will not keep out the sprite; but it certainly will shake the camera in the act of opening and closing, and on that account it ought straightway to be exploded, and better means ought to be applied (they are already devised) for covering and uncovering the aperture.

This trouble produced by reflections and otherwise, denominated the *Ghost*, is no new epidemic in optical combinations; the astronomer, or at least the astronomical optician, has frequently seen the pictures of two suns in his telescope, and has had to grind his objectives so as to get rid of one of them (the spirit of the other); but that a lens has *two burning points*, one on either side, the one produced

by reflection and the other by the transmission of light, appears to be a *novelty in optics*, to which our attention was first called by Mr. Henry Fitz, of New York, an astronomical optician of whom we Americans have a right to feel proud.

No sooner was this attention once called to the matter, than we verified the fact by burning a match cosentaneously on either side of a lens; and no sooner was the fact established than the consequences stood out in bold relief; the remedies of the evils produced became apparent, and the *Ghost* can easily be *exorcised*.

But woe unto the angle of aperture when the evil spirit runs away with swine!

[The existence and influence of these secondary foci arising by reflection from the cave surfaces of the lenses is most interesting and important. Although not entirely new to experienced opticians, it is in this article, by Professor Towler, for the first time, we believe, noticed. It is probable that a recognition of the fact, and a more careful examination of its operation, may lead to results tending to the removal of some defects at present existing in photographic lenses.—Ed. P. N.]

IMAGE ON THE RETINA OF A DEAD EYE.

THE *Evansville Journal* has the following:—

"We believe it is one of Mrs. Southworth's stories, in the *New York Ledger*, that represents a murderer as being convicted by a photograph of his victim's eyes, upon the retina of which was pictured the features of the assassin. Similar experiments, we are informed, have been made in France with great success, and mysterious murders unravelled through the instrumentality of Dagnier's wonderful art. Notwithstanding we had heard of these strange things, we were still under the impression that "dead men tell no tales," until a recent experiment has shaken our faith, and almost convinced us that though dead, men yet speak.

"On Sunday forenoon, Mr. Adams, a photographer of this city, at the solicitation of some gentlemen who had read of similar experiments in France, took his instrument and visited the scene of the late murder in German Township. This was some thirty hours after the murdered man had breathed his last. There was a great deal of dust flying and a great crowd collected, which materially interfered with the success of the experiment; but notwithstanding these unfavourable circumstances, Mr. Adams succeeded in taking a tolerably fair "negative." Upon this he has been experimenting, and yesterday we were called on to witness the results of his experiments.

"He had taken an ambrotype picture of the eye of the deceased, and then rubbed out everything but a single object apparently in the centre of the eye; this was placed under an ordinary magnifying glass. At the first glance the object appeared blurred and indistinct, but on getting the proper focus the outlines of a human face were at once distinguishable. The image was apparently the face of a man with unusually prominent cheek bones, long nose, and rather broad forehead. A black moustache was plainly seen, and also the direction of the eyes, which seemed to be looking at some object sideways. One of the eyes was as plainly seen as the eyes in a common ambrotype or ferrotype. Some who examined the image, thought the man of which it seemed to be a resemblance, had a Roman nose, and also had on a cap.

"Mr. Adams is continuing his experiments, but whether he will succeed in making any clearer developments, remains to be seen. His labours thus far are abundantly rewarded by the success which has attended his efforts, as it seems to us he has demonstrated that an object was pictured upon the eye of Mr. Herke at the time of his death, and that the object was a human face."

The Editor of the *American Journal* adds:—

"Some things are important, if true, others are interesting, in the language of the African, "whedder or no." The

above comes under the latter category. Mr. Adams is one of our subscribers, and, if he succeeds in getting any "clearer developments," we may expect to hear from him."

Proceedings of Societies.

GLASGOW PHOTOGRAPHIC ASSOCIATION.

THE annual meeting of this Association was held in the Rooms, Bath Street, on Wednesday, 20th ult.—Andrew Mactear, vice-president, in the chair.

Mr. EDMUND BRACE, the hon. secretary, read the annual report, of which the following is the more material portion:—

The Council of the Glasgow Photographic Association, in meeting the members at the close of the present year, feel much pleasure in being able to congratulate them on the success which has attended their first session, and which is mainly attributable to the good feeling and unanimity that has so happily subsisted amongst all its members. The Council find that during the past year forty-one new members have been admitted by ballot, and with the most lively satisfaction do they record the fact that there has not been even a solitary withdrawal. Two honorary members have also been elected. First, Dr. Taylor, of whose connection the society may well be proud; and second, Mr. Crombie, of New Zealand, whose pictures met with distinction at the Great Exhibition of 1862, and who is the author of one of the papers read before the society during last session. The past session was opened on the 4th September, 1862, with a very interesting address from the President, after which Mr. Vice-President Mactear gave a humorous account of a summer photographic excursion, and at the subsequent monthly meetings papers were read by the following gentlemen:—

Mr. John Stuart—"On Enlarged Pictures by Woodward's Solar Camera, and How to Tako Them."

Mr. J. N. Crombie, of Auckland—"On the Rise and Progress of Photography in New Zealand."

Dr. Taylor—"On Dioramic Effects produced on Photographic Pictures."

Mr. Vice-President Mactear—"On Photolithography."

Mr. J. Ewing—"On Manipulation, Developing and Intensifying the Negative."

The President—"On the Formation of Nitrate of Silver from an Impure Source, with Separation of Impurity; Do. from Pure Silver, with Proof in Favour of Atomic Theory; also, some General Remarks on the Sensitizing Bath."

Mr. A. Maenab—"On Copying and Enlarging Pictures." And

Mr. J. Stuart—"On Mounting Photographic Pictures."

It would be invidious to refer to any of these papers specially—many of them were admirably illustrated either by direct experiment or otherwise, all of them listened to with marked attention and interest, and most of them followed by animated discussions, in which the various suggestions brought forward were thoroughly elucidated. The Council would strongly urge that the greatest encouragement should be given to such discussions, feeling well assured that they cannot but be most conducive to the progress of the art; and being also convinced that every question, however trivial, put with a sincere desire for the acquirement of knowledge, will be answered not only with cheerfulness, but with the greatest pleasure, as the universal spirit of progression should, and they firmly believe will be uppermost at all the meetings of this Association. And here the Council may record their thanks to the professional members of our society, who have not only displayed an absence of jealousy (too often remarkable in professional men), but have always manifested the greatest readiness to communicate the progress of their daily experience, ever being animated by those broad and enlightened principles by which alone ultimate perfection can be obtained. In the session now commenced the Council are happy to announce that they have succeeded in securing the services of many whose attainments are well known and deservedly respected, and it is with great pleasure that they are enabled to lay before you the subjects appointed for discussion during the whole of the forthcoming session, and which they flatter themselves you will admit to be most interesting in the present and valuable for the future of that art, for the diffusion of which our society has been established. On the 19th February last, in compliance with the decision of

the Council, confirmed by your own resolution, a soireé, exhibition, and conversazione was held in the Merchant's Hall, when about 400 persons were present. Dr. Allen Thomson, F.R.S., kindly presided and delivered a very interesting address. Other addresses were delivered, and a collection of photographic pictures and other objects of interest exhibited to the meeting. The meeting was a decided success, although there were many defects in the arrangements (almost necessarily incidental to the first attempt at a meeting on so large a scale), which the Council have no doubt will be obviated at a future meeting. The Council might suggest as worthy of consideration, whether future meetings might not wisely partake more of an exhibition (to remain open for some time), concluding with a conversazione in preference to anything in the shape of a soireé. In a pecuniary point of view, this meeting has been a trifling loss to the Society, the receipts having been £23 15s. 6d. and the expenses £29 16s. 4d., showing a deficit of £6 0s. 10d., which was supplied from the ordinary funds. Finding the want of increased accommodation for the ordinary meetings of the Association, your Council, in November last, appointed a committee to look after more suitable rooms, and the result was that the meeting for the month of December was held at the Scottish Exhibition Rooms, Bath Street, and that place of meeting was continued during the remainder of the session, they trust, to the additional comfort of the members; at the same time, even that place leaves still much to be wished for in the shape of accommodation, and it would be very desirable that the Association should have rooms altogether its own, in which a library could be formed, pictures and apparatus permanently exhibited, and much other useful accommodation obtained, could funds be raised sufficient for that purpose. They would, therefore, direct the earnest attention of the Association, to this most important subject, and trust some plan may be devised, by which so very desirable a point may be attained. Your Council may here mention that towards the formation of the library two volumes on photographic chemistry have already been presented by Mr. A. Robertson, your worthy treasurer, and doubtless others will soon follow so excellent an example. Mr. Robertson has also presented an album for card pictures. Your Council feel great pleasure in reporting that the general funds of the Association are at present in a healthy condition, and from the treasurer's accounts it will be found that a balance of £2 18s. 11d. remained in hand at the close of the year. In resigning their trust into your hands, your Council would draw your attention to what appears to them to be a slight omission in the general rules of the Association, viz., a provision for the retiring of part of the Council at the end of every year, and they suggest that half their number should remain in the Council, the number of meetings each member has attended during the year determining who these shall be. Your Council may make another suggestion for your consideration, viz., the desirability of opening a correspondence with other photographic societies, especially those more immediately in our neighbourhood, with a view to the interchange of information and discovery. In the year that has passed much has been done towards the general advancement, from the American ghosts of our photographic friends at Boston to the more tangible ghosts of Professor Pepper in London. Globe lenses have been introduced, but it is doubtful if they exceed the triplet either in the straightness of their lines or speed of action, while the cost of the former far exceeds the latter. The Great Exhibition has closed, but it is doubtful if it has done much towards the advancement of photography, its treatment of which has certainly not given universal satisfaction. New processes have been introduced, amongst the most important of which may be mentioned the fuming by ammonia, and sulphocyanide fixing in the printing process, for which latter new papers have also been introduced in alabastrine and enamel, both producing beautiful results in the very high glazing of their surface, though not without difficulties in their manipulation. Great advancement has been made in the production of solar pictures, in the construction of apparatus for which much yet remains to be done. Copying and enlarging by transparency has also received its share of attention and been helped on its onward course. The application of photography to the lithographic process has been an object of not altogether unsuccessful research and experiment. Many new formulæ have been introduced with the view of insuring greater rapidity of action, and amongst all the progress that has been made, your Council think they may safely say that the first year of the existence of the Glasgow Photographic Association has not passed away without its

contributing its atom (however small) to the general advancement of the art.

The report having been unanimously adopted, and votes of thanks awarded to the officers for the past year, the following were elected for the ensuing year:—

President, John Kibble.

Vice-Presidents, J. Jex Long, and John Stnart.

Treasurer, Archibald Robertson.

Hon. Secretary, Edmund Brace.

Council, Andrew Mactear, Alex. Macnab, James Ewing, J. Bowman, J. Spencer, jun., and Dr. Prichard.

The meeting then separated.

THE LONDON PHOTOGRAPHIC SOCIETY.

The first meeting of the winter session was held on the evening of Tuesday, the 3rd inst., the Lord Chief Baron in the chair. The audience was unusually large and animated.

After a few observations from the Lord Chief Baron, the minutes of a former meeting were read and confirmed.

A variety of interesting objects were laid on the table—negatives from rapid dry plates, by Mrs. Spottiswoode; illustrations of the working of Dallmeyer's triple lens, by Mr. Hughes; specimens by Ross; the presentation print of Mr. Robinson; the presentation print of Mr. Williams; Mr. Hart's volumetric apparatus, &c. From the all-absorbing interest of Mr. Smith's paper and specimen pictures, other objects obtained but little attention, and were not, in fact, brought before the meeting.

Mr. SMITH then proceeded to detail the history of the alleged photographs of the last century, explaining how the matter first came under his attention, and the evidence he had been able to collect of their production, and reading extracts from the various documents having any bearing on the subject. We shall give a full statement of the case in our next; meanwhile, to render the discussion intelligible, we may now briefly recapitulate. About a year and a half ago Mr. Smith was in Birmingham, making some arrangements on behalf of the patent Museum, for the loan of Watts' first engine. Whilst in communication with Mr. Price, of the Soho Works, whose family had been the agents of the Boultons for two or three generations, his attention was called to some old pictures of a curious character. These, it appeared, were found by Mr. Price nearly twenty years ago amongst some tons of old documents in the private library of Mr. Boulton, which had not been opened for about fifty years. They consisted of some curious pictures in monochrome on paper, and of two pictures on silver plate, labelled "sun pictures," one consisted of a view of Mr. Boulton's house before its alteration in 1791, another of the same house after its alteration. Various documents in Mr. Boulton's papers referred to a secret process of copying pictures, the invention of a Mr. Francis Edgington, and also alluded to the necessity, for some purpose, of suppressing this invention. An old man connected with the Soho Works remembered pictures being taken by the members of the "Lunar Society," with which Bolton, Watt, Wedgwood, Davy, and others, were connected; these were done in a dark room. He said that Sir William Beechey, who was painting Mr. Boulton's portrait at the time, induced them not to publish the secret, as "it would shut up all the painters' shops." As a corroboration of the old man's memory, it was found that Beechey did paint a portrait of Boulton at the time. A camera had been found with the papers, which had not yet been traced to its present owner, but search was being made. In addition to the evidence derived from the Boulton papers, Miss Meteyard, "Silverpen," who was engaged in writing a life of Josiah Wedgwood, had found in papers placed at her disposal two photographs, which, from the evidence she had, appeared to have been taken by Thomas Wedgwood in 1791, and allusion to the lenses, chemicals, &c., employed, was found in the papers. The details would be published in Miss Meteyard's book in February. Allusion was made to the use of nitrate of silver, and to obtaining an image with great rapidity, but full details could not yet be given. Mr. Smith very lucidly had all the evidence he had collected before the society, and asked them to help in the further purpose he had, which was simply to arrive at the exact historical truth of this interesting subject.

The pictures were passed round for the examination of members. Some consisted of reproductions of pictures in monochrome and colour, by Benjamin West, Angelico Kaufman, and other eminent names. These pictures were on paper, some very large, done in two pieces, and altogether unlike any class

of pictures we knew; of the two pictures on silver plate about 7 by 4, and of the two pictures by Wedgwood, one about 8 by 6, a view of a breakfast table, having much the appearance of a faded silver print, and another similar in appearance, a small reproduction of a drawing.

The CHAIRMAN in proposing a vote of thanks, which was carried by acclamation, made a few observations on the slow progress of a new discovery until experience had developed its useful application. After which he retired, and the chair was taken by Mr. Bedford.

Dr. DIAMOND stated that he had called the attention of Mr. William Smith, deputy chairman of the National Portrait Gallery, a gentleman who, perhaps, knew more about art and pictures, than any other man in England. He at once said that these pictures (referring to those on paper), were not produced either by engraving, drawing, or painting, or by any method of which he had any knowledge; they bore no traces of handwork whatever. Mr. Smith had also lent him a catalogue which seemed to have a singular connection with this subject. It was a catalogue of works exhibited by the Polygraphic Society at 381, Strand, who had a method of copying pictures by Chemical and Mechanical Means, invented by Mr. Joseph Booth. The catalogue called attention to certain duplicate copies of pictures to prove that they had not been produced by hand, and also to the fact that the pictures would be ready for distribution during the summer, a very photographic kind of allusion. This Mr. Booth was a portrait painter of Lewisham, Kent, and there was a singular circumstance connected with a patent he obtained for manufacture of cloth, &c. He obtained an Act of Parliament, enabling him to secure his patent without divulging his secret, the specification being examined by two masters in Chancery, who were sworn to secrecy. It was quite possible that the " &c." might include this process of copying pictures. The catalogue had no date, but the collateral evidence pointed to 1792 or thereabout.

Mr. SMITH read an extract from the Patent Records, and a conversation ensued on the want of evidence of identity or connection between the polygraphs and those described by Mr. Smith.

Mr. P. LE NEVE FORSTER referred to the discrepancy between the published statement of Wedgwood and Davy in 1802, that they were unable to fix the images they then obtained, and the statement that Thomas Wedgwood produced the picture now before them in 1791.

A desultory conversation ensued, in the course of which Dr. DIAMOND remarked that it was possible that the print might have been preserved in its present state by simple washing. The early pictures of Mr. Fox Talbot were, he believed, so preserved, and afterwards by solutions containing common salt and bromide of potassium.

The question as to whether the pictures were produced by means of a lens and camera was then discussed, a general impression prevailing that those on silver plate and those by Wedgwood had been so produced, and that it was doubtful as regarded the large paper pictures.

Mr. SMITH referred to the statement of the old man he had mentioned, that the image was thrown on to a table in a dark room and then fixed with some kind of chemical.

Col. STUART WORTLEY thought it was probable they were produced by drawing the image of the camera obscura, as M. Claudet did some of his enlargements.

Mr. CALEY said Colonel Stuart Wortley seemed to overlook the fact that Dr. Diamond had already quoted opinion of a high authority, that these pictures bore no trace of such hand-labour, which M. Claudet's undoubtedly did. He had had an opportunity of speaking with Mr. Smith on the subject, than whom a more capable judge, it was well known, could not be found, and he expressly stated his conviction that such pictures would not be produced by impressions from steel, copper, stone, or other substance, nor by any method of drawing by hand. Mr. Smith had, perhaps, the most perfect collection of catalogues of sales and exhibitions of paintings in every part of Europe, arranged in chronological order, and his opinion of the date of Mr. Booth's exhibition was very valuable. It would seem that, in addition to what was going on at Soho, there was another, and distinct, although possibly similar process, going on elsewhere.

Colonel STUART WORTLEY asked if these pictures might not have been produced by some method similar to chromolithography.

Mr. CALEY said no; because the material and result bore no resemblance.

After some further conversation, Mr. SHADBOLT said, whatever opinion might be formed, as regarded the paper pictures, the silver plates were, in his opinion, unquestionably photographs. He had examined them carefully with a lens, and he was assured they were camera images from nature, and not copies of any kind of drawing. One of these, then, it appeared, took back the invention of photography to a period before 1791.

Mr. DEBENHAM called attention to the spots on some of the prints which had light and shadow, just as a photograph would have if spots or roughness existed in the original.

Mr. MALONE had examined them, as suggested, and came to the same conclusion. To refer to the paper pictures first:—The person to whom the invention was now referred, Mr. Edgington, was, it appeared, a person who was in the habit of painting, and from his allusions to the "dead colour," and "retouching," he saw no reason why these pictures should not have been produced by the brush. He saw nothing to connect them with the operation of light, and it was a gratuitous assumption that they were in any sense photographs. The fact that Boulton, Wedgwood, Davy, and others, were members of this Lunar Society, militated strongly against the supposition that light was employed, when they found Wedgwood and Davy years afterwards saying they failed to get an impression in the camera on account of the feebleness of the light. There was nothing to connect them with photography, and he did not believe they were photographs at all. Next, as to those attributed to Wedgwood. An impression prevailed that Josiah Wedgwood, the great potter, was also the photographer. Such was not the case. It was his uncle, Thomas Wedgwood, and it was this gentleman, who, with Sir Humphrey Davy, stated, in 1802, that no method of fixing sun pictures had been discovered. These pictures, certainly, or at least one of them, appeared to be a photograph, and reminded him of some of Mr. Talbot's early pictures; indeed, he had seen some of them with just the same objects. So far as he could see there was nothing to connect the pictures exhibited with the early date assigned to them. Then, with regard to the pictures termed Daguerreotypes, he must confess that with his knowledge and experience he should be afraid to call them Daguerreotypes, as some of the early pictures of Niepce, on metal, bore a startling similarity to the former. He had not carefully examined them, as it would require a better light to determine whether they were copies of drawings and not pictures taken with the camera before 1791. He felt that the evidence had entirely failed, and that if the matter had fallen into the hands of a photographer for examination, they would never have been brought before a photographic meeting, or have had such claims made for them. He sympathized with the gentleman who had shown such earnestness in the matter, but, as by admitting such unfounded claims they were detracting from the credit of gentlemen to whom the discovery belonged, he felt bound to protest against it.

Colonel STUART WORTLEY expressed a conviction that they might have been taken 15 years ago from a drawing.

Mr. MALONE: Precisely so. There were many other difficulties to be got over in supposing the use of a lens sufficiently perfect for the work. A gentleman, who he regretted was not present, and who, perhaps, was absent through motives of delicacy arising from his nationality, had remarked that iodine was not discovered until after the alleged date of these pictures, and that it seemed a miracle if it were possible for two distinct processes of photography to be discovered at that date, and then lost sight of.

After some further conversation, arising out of suggestions by Colonel STUART WORTLEY, that the alleged paper photographs should be compared with the original paintings,

Mr. SMITH reminded Mr. Malone, that he had not called the pictures on plate Daguerreotypes, but merely "sun pictures." The term Daguerreotype had been used by others, because of the similarity these pictures bore to Daguerreotypes.

Mr. SHADBOLT said, that if the pictures on silver plate were examined by the aid of a lens, it became clear beyond a doubt that they were produced with a lens and camera, and from nature, and as one was produced before the alteration of the house in 1791, there was a conclusive fact.

Mr. MALONE had not so examined, but would take Mr. Shadbolt's word, and pass that by; still, it did not prove that they were not produced at a later date.

Dr. DIAMOND said they were unquestionably from nature.

Mr. MALONE still did not see that the date was proved by that.

Mr. HART suggested, that some of the pictures which had

been thrown aside by Wedgwood, as not fixed, might have become developed by time since, and that one of these shown might have been in such case. In regard to the discovery of iodine, the chemists of that time had barilla, from which iodine was obtained, and might in some way have used it.

Mr. SMITH expressed a conviction that some of the pictures had become more developed, even whilst in his possession.

Dr. WRIGHT was glad that Mr. Malone had, by admitting that the silver-plate pictures might be photographs, given up his ease. They had, however, the evidence of Dr. Diamond, with whose opinion that of Mr. Malone could not, of course, be compared, that these were veritable photographs from nature, and one of them of a house which was pulled down in the year 1791.

Mr. MALONE feared he had not made himself understood. He had not examined the pictures, so as to come to a conclusion himself; but admitting or passing by that question, he did not see anything to prove the date when the picture was taken. It appeared to have been assumed on the hearsay evidence of an old man now dead.

After some further conversation, Mr. MALONE still expressed himself not satisfied, but at the same time fully appreciated the earnestness with which Mr. Smith had examined the matter, and hoped, if any word of apparent disrespect had escaped him, that Mr. Smith would accept his hearty apology.

Mr. PEARSALL had seen, at the Royal Society, the specimens which Wedgwood and Davy had explained, they could not fix. He remembered seeing in a somewhat rare volume—the *Journal of the Royal Institution*—an allusion by Wedgwood to the fact that the process might be of use for copying pictures on glass, and he remembered hearing Mr. Wedgwood regret the want of good means of fixing, arising probably out of his knowledge of some means of using it commercially. He next referred to the extraordinary effects which the Birmingham japanners and painters could produce in copying. He also added that those familiar with manufacturing houses could quite understand how a secret could be maintained, and even allowed to die out, rather than be communicated, if it were understood in the house that it was a secret.

Mr. JABEZ HUGHES suggested the importance of securing the camera as a link in the evidence. He thought at present all the exact evidence rested on the metal picture. Dr. Diamond and Mr. Shadbolt, two gentlemen eminently qualified to judge, had carefully examined the picture, and believed it to be the genuine production of a lens and camera, from nature. Mr. Malone had not examined it, but doubted it. The former gentlemen reasoned from their knowledge, the latter reasoned from his ignorance. It was not hard to decide whose opinion was in such case most valuable. The matter had been very carefully brought before them, and fresh evidence was promised. They had now to withhold a fixed judgment, but wait for fresh evidence. Unquestionably, there was a very strong *prima facie* case, and they were much indebted to the gentleman who had taken such pains to bring it before them.

The CHAIRMAN, after referring to the deep interest of the subject, and their indebtedness to Mr. Smith for the labour he had bestowed in collecting the evidence, announced that the beautiful reduced copy of Mr. Robinson's "Bringing Home the May" was a specimen of the presentation print, a copy of which members would receive early in the ensuing year. The Secretary would also hand to each member, on application, a very fine card portrait of their president, the Lord Chief Baron, which Mr. T. R. Williams was kind enough to present to the members. He proposed that the thanks of the meeting be offered to Mr. Robinson for his handsome gift of the negatives of the "May," and to Mr. Williams for the beautiful card portraits he had kindly offered to the members.

The thanks of the meeting to Messrs. Robinson and Williams for their gifts to the Society.

The SECRETARY announced that at the next meeting a paper would be read on "Photography in its Application to Military Purposes," by Mr. John Spiller, F.C.S., of the Royal Arsenal, Woolwich.

The SECRETARY also placed two bottles on the table, and read a letter from Mr. Malone, explaining an experiment on the photographic image. He had taken the blackened substance which constituted the photographic image, mixed it with gelatine, and then treated it with hypo. He afterwards submitted it to hot nitric acid, which did not, contrary to his expectation, dissolve it.

After a few words from Mr. MALONE, which were inaudible, from the meeting commencing to rise,

The SECRETARY said there were various other matters which had been intended to bring before the meeting, which, at this late hour must, however, stand over.

Mr. C. HANBURY then hastily illustrated the working of a washing apparatus, and

The proceedings terminated after 11 o'clock.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, November 4th, 1863.

A LIVELY dispute is going on between Messrs. Marquier and Mirvan, respecting the priority of the photolithographic process submitted to the academy by M. Mirvan. In support of his claim M. Marquier submits—1st, an official copy of the specification of his patent and of those taken out by M. Mirvan. 2nd, of a certificate attesting that in May, 1862, he sent to the Great Exhibition of London a frame containing proofs taken by his process. 3rd, of a letter from M. Husson, brother-in-law of M. Mirvan, declaring that in the impossibility of his obtaining satisfactory results, he desired to enter into communication with M. Marquier, and negotiate for the purchase, wholly or partially, of his discovery. It is true that the patents and additions of M. Mirvan are anterior to M. Marquier's patent. But the process presented to the academy by M. Mirvan is not the process described in his second and last addition; it is simply and purely, with two slight differences, M. Marquier's process. M. Mirvan has merely substituted gelatine for gum, and bichromate of ammonia for bichromate of potassa.

M. Poitevin has published in *Les Mondes* the following letter on the matter in dispute:—

"In the interest of truth, I believe it to be my duty to protest against M. Marquier's pretensions to the invention of a new process, and especially against the validity of the patent he took out on the 18th of June, 1862, for working this kind of printing in France, which he realized at Cuba, in 1861.

"According to the description given, he employs, for photographing on stone, the bichromates and gummy, or gelatinous organic matters.

"On the 27th of August, I took out a patent precisely for this very application of bichromatized organic matters, and, consequently, I anticipated M. Marquier's patent seven years. As is well known, my patent has been constantly worked; and, moreover, my invention has been recognized and appreciated under many circumstances, which I believe it is unnecessary to mention here.

"Rest assured, Mr. Editor, that it is in the interest of both parties that I make these observations, and that I have no other desire than to avoid disputes in future, always vexatious, to which the working of M. Marquier's patent must give rise."

On this letter the Editor of *Les Mondes* has the following remarks:—

"We are not called upon to decide upon the differences already noticed between M. Marquier and M. Poitevin's processes. It is not for us to say whether these differences are sufficient to warrant a new patent; but we may say that in the way M. Marquier views the matter (who, moreover, has no intention of working his patent commercially), that the possibility of his operating with a negative instead of a positive, which M. Poitevin has necessarily required—constitutes a truly essential difference."

M. Gammé has made some suggestive remarks upon a phase in landscape photography well worthy of being carefully tested. He says that frequently, when taking a view of an edifice, or landscape, or other object, during the afternoon, that the portion upon which the sun's rays had shone

during the morning, but which, at the time of photographing it, was in the shade—this portion, he says, came out in the picture with much more detail than if taken in the afternoon when the morning rays of the sun had not shone upon it. In the first case, the detail has come as well in the shade as in the light, without a very long exposure; in the second, it seems as if the shade was more opaque. Is this an error, or is it to be attributed to the phosphorescence of objects, or storing up of light, which has been so ingeniously suggested by M. Niepee de Saint Victor? Can it be retained in the objects so long? What induces me to believe so is, that if it happens to rain between the time upon which the sun has shone upon the objects and the time of photographing the same, the effect described no longer takes place, for the shade lacks detail; it would seem as if the rain washed out the light from the object.

MOUNTING PHOTOGRAPHS.

Sir,—As every hint of a practical nature may be of use to some one or more of your numerous amateur readers, I send you my mode of mounting proofs, which I have long found easy and successful.

Into a small beaker glass I put 2 ounces of cold distilled water, and place in it 48 or 50 grains of Cox's refined gelatine. When this is sufficiently softened (usually whilst I breakfast), it is heated by a spirit lamp till entirely dissolved, and the solution is then placed in a common jelly-jar, filled with boiling water to maintain its fluidity. The mounts being ready, I sponge them lightly with cold water on the face, and laying a print on a smooth pad of clean blotting paper, brush over it with a flat hog's-hair tool the solution of gelatine, crossing it in all directions till fully wetted, and taking especial care that the edges are so. When it ceases to curl or cockle and lies perfectly flat, I lift it carefully and place it on the damp mount, putting over it a piece of clean blotting-paper, and then rub it down firmly with an ivory folding-knife, commencing at the centre and proceeding thence to the edges and corners. Unless the paper be very thick, it will at once adhere firmly, but should a corner not do so, I gently raise it and apply a little more gelatine, rubbing it down again forcibly with the paper-knife, the blotting-paper being of course interposed. In this way I find it easy to mount prints of every size, from that of a carte to landscapes 12 by 10 in. When nearly dry, I place them face to face, with a sheet of clean writing-paper between them, under a weight till entirely so. A pile of books, or a board and a few iron weights answers the purpose.

If this is at all likely to be useful, its insertion will oblige your occasional correspondent,

ALIQUIS.

GLASS HOUSES AND DISTRICT SURVEYORS.

Sir,—I have just learned something by experience, though nearly too late and at too great cost. In removing my glass-house to more commodious premises, where I get all the sun for printing purposes, I was not a little astonished at receiving notice from the District Surveyor to pull the same down when nearly complete. He called it a wooden house, though at least three-fourths are glass. I went on with the work, however, and at last the Surveyor came and stopped the workmen, telling them they were subject to a fine of fifty shillings or a month's imprisonment. This has left me helpless. I was under the impression that a house not having foundation, or attached to the dwelling-house, would pass. However, I find now, to my loss, that such is not the case. Some time back there was a drawing of a house in the NEWS, a very low sum being stated for the erection of the same; but it would not be allowed, and I therefore send you the following information:—All such houses as are used for photographic purposes must be, where no brickwork is desired as foundation, composed of the following parts:—Glass-frames, sashes, and doors: no walling must be attempted by boarding up any part, or it will be called a wooden house, and thereby be subject to come

down. Now, I am aware of many an honest man thus nearly ruined by being compelled to pull down his glass-house, or go to some very great expense to meet the law. I therefore thought I would send you a line or two on the subject, leaving it to your own discretion to do with the same as you might think fit. Believing something inserted in the NEWS to this effect would prove welcome to many who have never seen the Act, led me to write this hasty sketch. Believe me, Sir, yours very obediently, G. R. GILL.

43, Islip Street, Kentish Town, Oct. 28th, 1863.

[We believe that the arrangements to which you refer, vary in different districts, according to the Act of Parliament under which they are locally governed. In all cases the District Surveyor should be consulted prior to commencing any erection.—ED.]

Talk in the Studio.

COLLODION FOR WOUNDS.—Mix one part of crystallized perchloride of iron gradually and with care, so as not to boil, with six parts of collodion, and a good hæmastic for wounds, leech-bites, &c., is produced. The composition should be of a yellowish red; it is perfectly limpid, and produces a yellow and very elastic pellicle. This hint to surgeons comes from Antwerp; it might be useful also to men who shave either themselves or others.—*Scientific American*.

THE DOUBTFUL LIKENESS.—The Paris correspondent of the *Daily Telegraph* is either a photographer, or an admirer of the art, as he constantly makes allusion to its varied use. He gives recently an anecdote of a portrait which was evidently not a striking likeness:—"Appropos of photography, last night one of the corps de ballet at a small theatre here was showing her portrait under which she had written in large characters her name and address. "Do you think it like, Fifine?" she asked of one of her sister-danseuses. "You forget I can't read," was the doubtful compliment to the artist. But the story does not end there. Fifine, laughed at for her ignorance, was determined to re-establish her character. "Come with me, and I will show you the autograph of Victor Hugo," said a friend, a few minutes later. "Oh, how I should love to see it; is it like?" was the exclamation of the unlucky Fifine.

CLUB PHOTOGRAPHS.—The same authority, speaking of a new Jockey club, in Paris, says:—"The only novelty I have as yet discovered in this new institution is that the photographic portraits of all the members of the club are displayed in one part of the entrance-hall so that the wearied tradesman or irritated creditor may sit and frown at the copy while waiting for the original. Let us hope, too, that the members as a body are good looking, for to pass through a "Chamber of Horrors" would spoil any dinner. Besides, such awkward remarks might be made, of the same sort, for instance, as that which was recently made by an English nobleman to the Emperor of the French, who, knowing my lord to be a soldier, had treated him to a review—a display perfectly thrown away on the "worst officer."—I quote the adjutant in her Majesty's Lifeguards—Green. "Well, Lord —, what do you think of my soldiers?" Well, Sir, I think they are the very ugliest lot I ever saw."

BLACKING THE BRASS WORK OF LENSES.—One or two correspondents have recently asked for information as to the method of producing the black colour on the polished part of lenses, stops, &c. The dead black may be produced in various ways, the simplest being the application, cold, of a mixture of lamp-black and common spirit varnish. This will, of course, rub off with friction. The polished black is produced by what is termed "chemical bronze," which is generally supplied by chemists ready for use, each maker probably having his own precise formula for its preparation. It simply consists, we believe, of a dilute solution of bichloride of platinum. The best strength we cannot state, as we have not had occasion ourselves to use it. Bichloride of platinum is prepared in a manner similar to chloride of gold, by acting on the metal with nitro-hydrochloric acid; the acid solution is then evaporated to dryness, which leaves a reddish brown deliquescent substance readily soluble in water. If used too strong, its action is too rapid and corrosive; if too weak, it refuses to act at all, especially on some samples of brass. It is best applied to the metal immediately after turning, so as to have a chemically clean and untarnished surface. It is applied with a camel's hair pencil. When the operation is complete, the surface is brushed with a little black lead. [Since

writing the above, we have been furnished with the following formula:—4 drachms of bichloride of platinum, 1 grain of nitrate of silver, in 6 ounces of water. This is said to answer well.—Ed.]

THE TRIPLE LENS.—The following remarks by the Editor of the *Journal of the Bengal Photographic Society*, furnish gratifying proof that the opinion we have always expressed of this lens find full confirmation in India:—"The use of triple combination in lenses for ordinary landscape work has become so common, and, in some respects, possesses such advantages, that we shall make a few remarks on the subject, in the hope that they may be of use to some of our readers. The favourite form of lens at present is the triple combination, the advantages of which are that—*first*, it includes a larger horizontal angle than the old single lens; *second*, that it gives greater depth of focus with a large aperture; *third*, the focal length is about one-fifth less, which, combined with the possibility of using a full aperture without any very serious falling off in definition towards the edges of the plate, make up a total of advantages not to be found in any other lens. The introduction of this form of lens has rendered instantaneous photography, on a tolerably large scale, possible, and the photographic world is indebted to Mr. Dallmeyer for this and many other valuable improvements in the form and principle of photographic apparatus. We have recently tried some experiments with a triplet lens by this maker, stated to be for plates 10×8. The focal length is a trifle under 12 inches, and we find that, with the middle stop it gives fair definition to the edges and corners of a 12×10 plate. We confess of being greatly astonished at this, for the idea that a lens could be made to cover a plate equal to, or exceeding its own focal length never entered our imagination. An old landscape photographer will not fail to see the immense advantage gained in angle by what we have stated, and we shall take an early opportunity of exhibiting a picture which we hope will make the gain apparent. The actual angle included by the above lens we find to be as nearly as possible 45 degrees, or 10 degrees more than the old lens gave. This is a gain of nearly one-third, combined with such an increase in rapidity that, with ordinary skill, there is nothing to prevent any good photographer from taking instantaneous views of the sea, and landscapes generally, with figures and life in them, such as no skill, however great, could possibly have accomplished a few years ago. Looking at what has been done in a few years, we do not despair of seeing lenses made which will include a still greater angle, and give instantaneous pictures upon plates 15×12 or even larger. Increased rapidity is more to be hoped for in the optical than in the chemical branch of photography, for it is difficult to conceive anything more sensitive than the collodion film. All that it requires is a free admission of light, there is plenty outside, but we have hitherto been obliged to shut it out to meet focal difficulties."

To Correspondents.

- J. W. R.**—There is no especial work published in this country on card pictures. The various recently published manuals contain information on the subject, and our pages contain all improvements and modifications made from time to time. Our ALMANAC, which will shortly be published, will also contain special advice on the subject.
- H. T. B.**—We prefer the interior of the dark room to be black or a dark colour, so to reflect the least possible light, if it by chance get in unobserved. 2. The acetate toning bath most readily gives purple black tones.
- A PUPIL OF THE NEWS.**—The splitting of the film may proceed from many causes. Imperfect cleaning of the plate, or coating it when slightly damp, will cause it; under-exposure and over-developing and intensifying is a very common cause; an acid bath is favourable to it. Clean the plates well, and use them quite dry, expose sufficiently, do not dry the plate by the fire, but let it dry spontaneously. The cause may be sometimes in the collodion; but we think not in this case.
- DEKLA.**—If negatives are kept in a dry place, with blotting paper between, they will not suffer injury. 2. If you add sufficient common salt to your washing waters you will throw down all the silver. Rapid agitation and the addition of a little nitric acid will aid the entire precipitation. 3. Gum may be used for mounting if used fresh, but it is apt to become acid and dangerous.
- E. S. D.**—We prefer No. 2, as being more rapid in action and giving greater depth of definition. We think its superiority is worth more than the difference in cost.
- HENRY NUTTS.**—The proposed plan of your glass room appears very good. Let the glass in the sides be continuous and not divided by a space of wood.
- C. W. F.**—The cuttings from fixed prints do not contain much silver; but we believe they are worth about fourpence per pound. 2. The residues of developing solutions contain silver sufficient to repay preserving them.
- J. J.**—Mr. Pouncy is the only person who undertakes the process in printers' ink at present. We do not know his charges. Probably Mr. Dallas's process will give you the best results of any photo-engraving process.

- G. S.**—The glass received is not a true orange tint, but a brown. It would not be perfectly safe in a strong light.
- G. W. O.**—If the opal mullage be in the habit of turning acid, as your second experience indicates, it is certainly not safe for photographs, and it is right, as you say, that the caution should be given.
- J. L. PRESTON.**—For purple tones, we prefer the acetate bath, and for deep blacks, the lime bath, as we have recently described it. You must, to get good tones, have a good negative and print and tone deeply.
- A CONSTANT READER.**—Methylated spirit may or may not be pure of its kind, different samples having different qualities. Spirits of wine should not be used in albumenizing paper at all.
- LUX.**—There is no danger of a preliminary coating of India-rubber injuring the nitrate bath. 2. The dark slide is not likely to injure a tannin plate when dry, unless the wood be sufficiently new to give forth some resinous smell. 3. A half-dried plate put into the slide will assuredly have a mark, as the rate of drying or evaporation is checked, and a different result produced.
- T. C. CONSTANT SUBSCRIBER.**—If your negatives fit your printing frame tightly, that would unquestionably be an occasional source of cracking, as sufficient room for expansion in changes of temperature is desirable. We have occasionally known such a thing as a negative cracking in the printing frame, but not often. It generally arises from some unequal pressure as well as change of temperature. See that the frames are not warped, and that the pressure is true and even, and use thin patent plate. Also do not subject the glass to greater change of temperature than you can help. 2. Reproducing a negative by means of superposition on a dry plate will have a greater tendency to give hard results than by reproducing on wet plates in the camera; if you use the dry plates, be careful to avoid under-exposure. 3. Stop out the spot in the wax-paper negative by using a little opaque water colour. 4. Metallic spots are generally a defect in the original paper; a fresh sample is the best remedy. 5. A bright red heat, approaching whiteness, is necessary to melt chloride of silver when a proper flux is present. Metallic silver is said to require a white heat, or a temperature of about 1,873° Fah. to melt it.
- HENLEY.**—If the deposit be sulphide of silver, which is probable, nitric acid will dissolve it, forming nitrate of silver and sulphate of silver. If it be gold, which is possible, a mixture of nitric and hydrochloric acids will dissolve it.
- NOTTS.**—Your design seems very good. We should place the background at the west end; and choose angle No. 2 for the pitch of the roof, as most likely to give a satisfactory light.
- OPEN AIR PHOTOGRAPHY.**—Where a tent or dark box is available, we should prefer wet plates. The chief advantage of dry plates is portability.
- HINDOO.**—Take out some collodion iodized, and some plain. A good bromo-iodized collodion, with cadmium, will keep for years in this country; how long in India, we are uncertain; possibly, if kept in full bottles in the dark, twelve months. If you are skilled in preparing your own collodion, by all means make it there; pyroxyline will keep for many months, sometimes years; do not keep it air-tight. The paper will be almost certainly read at the next meeting. You can receive the NEWS regularly in Bombay; your best plan will be to subscribe here before starting. Communicate with our publisher.
- E. S.**—We have not ourselves tried the especial formula, but we have worked enamel paper on still weaker baths with success. Probably there is some difference in the samples of enamel paper employed.
- PARVUS.**—Any good collodion, yielding a fine textureless film will answer for microscopic photographs, but we cannot certainly tell you whose sample is most suitable. We have seen some which would answer, of Keene's. Do not dilute with ether only, but with absolute alcohol as well. The addition of a little tincture of iodine will be an advantage to most samples.
- GETTSBURG.**—Ebonite, as made by Silver and Co., has proved, in our hands, very satisfactory, and has not contaminated the silver bath. 2. It is very strong and tough. 3. It is a form of vulcanized india-rubber submitted to peculiar treatment. The greater part of the sulphur employed in vulcanizing is subsequently eliminated by exposure to great heat. 4. It is very easy for each purchaser to get his ALMANAC bound; but we are not sure that it will answer the purpose of our publisher to issue any so.
- T. RATCLIFFE.**—We will forward the letter, and hope to get more information.
- A. BROTHERS.**—The print and stamps have been handed to our publisher, and will receive due attention.
- W. ABERDEEN.**—We have answered your question in another paragraph. You have simply to evaporate your acids, and the residue is the chloridic; there is no nitrate formed, the nitric acid simply aiding the operation; Use the solution dilute; the exact strength we cannot state; a few experiments will inform you.
- R. C. LOBB.**—The print you have sent us is most charming, and proves the skill and taste of the photographer, as well as the excellence of the chemicals.

Several Correspondents in our next.

THE STORY OF THE EARLY PHOTOGRAPHS.

THE history of the photographs supposed to have been produced half a century before the recognized birth of the art, and which, some six months ago, we had the pleasure of first bringing under the notice of the photographic world, is not yet completed. An interesting narrative, affording strong presumption of the legitimacy of the claims made, has been given to the public; but, as yet, some links are wanting in the evidence before it can be admitted to have the force of absolute proof. We shall here briefly put the statements of Mr. Smith, which he confirmed by voluminous extracts from authentic and original documents, into a brief consecutive narrative for the information of our readers.

Before doing so, we must call attention to the somewhat singular fact, that there are three, if not four, distinct classes of pictures, each by a distinct process, and, probably, by a distinct person, each with more or less of evidence believed to be photographs, each believed to be produced in the last century, and all more or less associated with the same names of persons known to have interested themselves in the production of pictures by the agency of light. We have a picture on a silver plate, believed by competent judges to be an undoubted photograph from nature, of Mr. Boulton's house, alleged to have been pulled down in 1791, and a similar picture of the same house after its alterations. We have large pictures on paper, some three or four feet long, which are monochrome copies of paintings, by a process which the ablest judges of pictures assure us bears no resemblance to any known method of pictorial production. Both these and the former are found amongst papers in Mr. Boulton's library, stated not to have been disturbed for upwards of half a century. Then we have two pictures, alleged to be photographs, one of them undeniably so, found by Miss Meteyard, amongst the papers supplied to her as material from which to draw in writing a life of Wedgwood, the great potter. These two pictures are stated to have been produced by his son about 1791, and documents of that date refer to the lens, camera, and chemicals used in producing such pictures. Then we have again a catalogue of about the same date of an exhibition of pictures, called polygraphs, produced without hand labour, by "chemical and mechanical means." We have no specimens at present of these latter pictures, nor have any photographic claims as yet been made for them; but the allusion comes in as an interesting and collateral fact, which may bear upon the others.

Upwards of twelve months ago, Mr. Smith, Curator of the Museum of Patents at South Kensington, had occasion to visit the Soho Works, at Birmingham, on business connected with the exhibition of Watt's first steam-engine at the Museum. Whilst in communication with Mr. Price, the agent of the Boultons, a gentleman whose family has occupied the same relation to the Boultons for two or three generations, his attention was called to certain curious-look-

ing pictures, which Mr. Price had found about twenty years ago amongst old papers and lumber in the private library of Matthew Boulton, the said papers and library not having been disturbed for fifty years before. He also pulled out of a drawer two plates like Daguerreotypes, packed between two pieces of board. One appeared to be a plain plate; the other had the picture of a house, and was labelled "Sun Picture of Mr. Boulton's House before the Alteration in 1791," and also bore the initials "J. W." This descriptive inscription was written, it appears, by an old lady, a member of Mr. Price's family, who remembered the house before its alteration in 1791, and at once recognised it. The other plate had since been found to contain an image of the house in its present state. This old lady as well as another old retainer of the Boulton family, both now, we believe, dead, also spoke of remembering the picture being taken by placing a camera on the lawn. The old man referred to the production of pictures by members of the "Lunar Society" as a common thing; stating that they used a dark-room and threw the images on to a table, and fixed them by some chemical. He also stated that the practice was discontinued, and the secret suppressed, at the request of Sir Wm. Beechey, who was painting a portrait of Mr. Boulton, who said that its promulgation would "shut up all the painters' shops." This is, as Mr. Maloué remarked, merely the hearsay evidence of an old man now dead; but there is the singular corroboration of his veracity and memory in one respect in the ascertained fact that Sir Wm. Beechey was engaged at the time referred to in painting Mr. Boulton's portrait. Mr. Price also found, at the time when this library, with the dust of half a century, was first invaded, a camera, which was given away to someone, and for which the search instituted has not hitherto been successful. So far as these pictures on silver plate are concerned, little doubt appears to exist that they are photographs, and that they are from nature, not copies of other pictures. The examination of the images by capable judges, Dr. Diamond, Mr. Shadbolt, and others, aided by magnifying power, issued in a decision that they were the images given by a lens from a natural object, and not copies of any kind of drawing, which must always possess a distinct and conventional character. The only weak point in the evidence of the age and authenticity of these pictures, is the want of decisive proof that the picture is really a view of the house before its alteration; and that this alteration was made in 1791. These two points established beyond a doubt, and the evidence is already strong, there is no room, we think, for further question of the fact that photographs on silver plate were produced half a century before Daguerre's discovery. By whom is not yet well established.

In regard to the paper pictures, the question becomes more complicated and difficult. It is by no means certain that they are photographs. They are certainly not photographs by any process of which we have any knowledge. But whilst they are unlike any class of photographs, we know

on the evidence of the Deputy Chairman of the National Portrait Gallery, an undeniable judge of such things, that they are equally unlike any class of painting, drawing, or engraving we know; and there are certain presumptions in favour of their photographic character. They are in monochrome; they are reversed or left-handed, as camera copies would be; they were produced by a secret process, and produced cheaply; they were in the possession of and produced by persons who were known to be associated with early photographic research; they have certain minor defects, which suggest photographic operations; one of them being large, is produced at twice, on two pieces of paper, and the colour or tone of the two halves varies in the manner photographs so produced are so often seen to vary. They have no appearance of any kind of engraving or lithograph, nor any class of drawing or painting. They appear to be on a kind of albumenized paper, and the colouring matter or image wipes away readily and cleanly, having little coherence or adherence. Against the presumption of their being photographs, the argument of chief weight, to our mind, is derived from the perfect definition in pictures of such large size. If they are photographs, we have made no progress in reproduction, possibly retrogressed.

There are, however, some very singular facts in connection with them which seem almost inexplicable. That they were produced by some rapid, cheap, faithful, and secret process is certain, and that the secret was for some reason suppressed is equally certain. The process appears, from the documentary evidence read by Mr. Smith, to have been discovered by Francis Edgington, a person in the employment of Matthew Boulton. Various bills or invoices for copies of paintings, by popular modern masters, by this secret process, are discovered, and also allusions to a Mr. Barney, who finished these copies with colour so as to resemble the original paintings, the work appearing to have a tolerably extensive demand. That a certain, rapid, permanent, and cheap method of reproducing pictures should have been suddenly entirely suppressed and the secret suffered to die out, appears in the present day almost inconceivable. But such appears to have been the fact, and we next find a most singular document bearing on this subject. It consists of a rough draft of a letter, in Matthew Boulton's handwriting, with one name, often recurring, most carefully obliterated. This name can, however, be clearly made out to be Edgington. The letter is addressed to a noble lord, and refers to a proposed pension of £20 a year to be given to Edgington, in consideration of the suppression of his invention. Mr. Boulton deprecates this on various grounds. In the first place, the man is his servant, and has already been duly paid for his services by a regular salary; next, that the payment of the pension will have a tendency to keep alive in his mind a matter which it is desirable he should forget; next, that he can better bind him to secrecy by considerations of attachment and gratitude to his master, and rewarding him himself necessarily; and next, that he would like the reward proposed for his servant to be given to himself, proceeding to develop a little job that we are not called further to detail or comment upon here. Whatever the process, we have it distinctly set forth in the document, that for some reason arising out of interested motives the method had to be suppressed and the secret suffered to die out.

The evidence is silent as to the photographic character of the process, and we can only deduce that from the character of the pictures and from the associations and traditions connected with them.

The third class of pictures has been brought to light more recently, and through a different channel. It consists of the pictures, which, as we announced a few months ago, had been found by Miss Meteyard amongst the old papers furnishing materials for the life of Wedgwood, upon which she was engaged. There are two pictures presumed to be photographs: one of them is so undoubtedly; the other, a copy of a drawing, is more doubtful. The genuine one is a picture of a breakfast service duly set out; it looks like a faded

silver print on paper. Miss Meteyard believes that she has sufficient evidence to attribute these to Thomas Wedgwood, the son of Josiah Wedgwood, the potter, and that they were produced in 1791. Amongst the documents are allusions to a camera, lenses, and chemicals for the production of such pictures. For the full details we must wait, however, until Miss Meteyard publishes her volume, which will appear in the course of two or three months. The point to be established here is the date of production, and of that at present we have no direct evidence.

In 1802, we find Wedgwood (not the same member of the family to whom Miss Meteyard attributes these pictures, we believe) and Davy reporting in the *Journal of the Royal Institution*, that the images of the camera obscura were too faint to produce, in a moderate time, any effect on their silvered paper, and that the pictures they did obtain by using the solar camera, they were unable to fix, as the paper darkened in sunlight even after washing well in water. Mr. Peter Le Neve Foster objects that if Thomas Wedgwood had produced and fixed camera images in 1791, it is very strange we should have the statement made to the Royal Institution in 1802. Mr. Malone, who assumed the opposition on all points, admitted that one of these pictures was a photograph, suggested that it looked very like one of Mr. Fox Talbot's earliest pictures, and he thought he had seen a similar subject. Dr. Diamond informs us that he has since received almost a duplicate of the picture from Mr. Talbot. This part of the subject also awaits further evidence.

The catalogue of the Exhibition of Photographs, lent to Dr. Diamond by Mr. Wm. Smith, affords another singular illustration of the possibility of an invention dying out and being forgotten. Whether any direct connection subsists between these and the alleged photographs, remains to be seen. But here is a catalogue of an exhibition of paintings held in the Strand some time about 1792, in which a method of copying paintings by "chemical and mechanical means" is referred to. Attention is challenged to duplicates which prove by their identity in all respects, that they are not the product of hand labour. The process is the invention of a Mr. Joseph Booth, a portrait painter; and we find that about the same time he obtained a patent for a process which he did not describe, a special Act of Parliament being obtained for the purpose. The patent was supposed to be for a method of manufacturing certain fabrics, but whether it included picture making, there are no means of ascertaining with certainty. Here is another instance of a cheap and faithful method of copying paintings by chemical and mechanical means, which appears to have died out; and, although little more than half a century has elapsed since, as yet no specimens are forthcoming, and the matter appears to have been almost forgotten.

There is not at present any certain connection between the last-mentioned pictures and the alleged photographs; but between each of the three first-mentioned classes, distinct as they are, there is the connection arising from their association with the same names. Tradition speaks of the photographic experiments of the "Lunar Club," associated with which we found the names of Davy, Boulton, Watt, Wedgwood, Priestley, and other savans of the day. In one of the documents referring to Edgington's process, we also find allusion to certain of the pictures for Mr. Wedgwood; but we do not find any direct mention of the name of Watt, as had before been supposed.

At present, any definite decision must halt and await further evidence. There is a sufficiently clear *prima facie* case to afford a strong presumption and warrant further inquiry. We admit fully the apparent improbability of such a discovery as photography being made and then being suffered to sleep, perchance to die. But against this we have the fact that an important discovery of some kind was made and then suppressed. Besides, probability cannot be permitted to weigh against evidence, and upon sufficient evidence alone can the laurels of discovery be removed from the brows which have hitherto worn them. To Mr. Smith

all honour is due for the perseverance and industry with which he has pursued the inquiry to its present stage, and for the honourable and high-minded impartiality with which he has brought forward his evidence, presenting it in the spirit of the philosopher not of the partizan, seeking above all things to establish the truth. Possibly the most satisfactory plan at this stage of the proceedings would be for the Photographic Society to appoint a committee to assist Mr. Smith in the prosecution of the inquiry. We hope shortly to record the conclusions of further research.

THE WINTER SESSION OF THE SOCIETIES.

THE season having come round in which the various Photographic Societies hold their regular meetings, a brief hint or two, not so much novel, perhaps, as important, may be worth repeating. The Societies have done good work hitherto in aiding the progress of the art, and affording pleasant occasions of intercommunication amongst members. We are desirous of seeing them continue the good work, and, by systematizing it, become more useful, more pleasant, and, probably, more permanent.

One great failing in some Societies has been the absence of a definitely announced subject, upon which members could come to listen or to speak, prepared by previous thought and experiment. When members hear of the subject only when they reach the meeting and hear a paper read, the discussion must necessarily be desultory and uncertain. If, on the other hand, a subject be announced a month before-hand, it is the fault of members themselves if they do not secure an exhaustive discussion. But better still than preparing one month before another, is the plan of preparing for the whole session in advance. When this plan is adopted, a varied and complete range of subjects can be secured, and members can come fully prepared for a most exhaustive discussion, should the subjects require it. A programme of this kind need not exclude topics of current interest, arising during the progress of the session, from receiving attention. The stock subject of the evening will not, in many cases, evoke much discussion, and on most occasions, opportunity will occur for the passing examination of some subject of immediate interest, or for desultory conversation on a variety of minor photographic matters; after the five-act legitimate drama may come a lighter piece, or *divertissement*. An illustration of this system of providing a certain and definite subject for each evening in the session is furnished by one of the most energetic and active societies in the North. The Glasgow Society have recently issued their programme, which we will reproduce as an example for others:—

PAPERS TO BE READ AT THE USUAL MONTHLY MEETINGS DURING THE SESSION.

1863.	
October 23rd	"Improvements on the Solar Camera" (with Illustrations).—By JOHN STUART, ESQ.
November 11th	"The comparative value of the Daguerreotype—Collodiotype and Calotype—Photographic results (as regards Portraiture) in point of Beauty, Permanence, &c."—By JAMES EWING, ESQ.
November 25th	"Experiments in Development Printing."—By GEORGE SHADBOLDT, ESQ., of London.
December 9th	"On certain Rapid Dry Processes."—By THOMAS SUTTON, ESQ., of Jersey.
1864.	
January 13th	"The application of Artificial Light to Photographic Purposes" (with Illustrations).—By J. W. STONE, ESQ.
February 10th	"Iron Developers and Intensifiers."—By G. WHARTON SIMPSON, ESQ., of London.
March 9th	"About Printing and Toning."—By C. JABEZ HUGHES, ESQ., of Ryde, Isle of Wight.
April 13th	"Chemical Combination and Decomposition."—By DR. WALLACE.
May 11th	"On Copying and Enlarging" (with Illustrations).—By ALEXANDER MACNAB, ESQ.

Other Important Papers on various interesting subjects are promised, for which extra Meetings will be arranged, and the dates thereof duly announced.

It will be seen here that for other important subjects extra meetings will be convened, so that nothing interesting will be excluded by having stock subjects arranged. An excel-

lent method to aid in securing papers is furnished in a bye-law of one of the London Societies. It is to the effect that each member of the committee is bound to provide at least one paper during the session. It is not necessarily imperative that he should read a paper himself, but he must do that or provide a substitute, so that the society cannot meet, as sometimes happens, without any subject whatever before them. It appears to us that, in any case, a paper should be provided and announced a month in advance, at least, and much longer where it is possible.

There is another change we should like to see. We should like to see the discussions more general and less confined to two or three persons. To secure the facilities and inducements for this, a little more attention to the recognised laws of debate is desirable. A very offensive feature of some meetings, we know, is the habit of one or two persons jumping up and speaking half-a-dozen times on the same subject, and that often with a captious motive or in a captious tone. This frequency and persistency in speaking, and this tone, have a most detrimental effect, in the first place, in not affording opportunity to less eager and apt speakers, and in deterring those who are more modest and timid. Long speeches are less common in photographic meetings; but there are occasionally speakers who do not know when to leave off, and exercise an injurious influence on meetings. We do not mean, in deprecating frequent speaking, to entirely condemn the conversational discussion, which is in some cases unavoidable, and often very interesting, or the necessary explanation which may arise, but the iterated and irrepensible speech-making which is so offensive.

There is another hint we would offer here to photographers at large, as well as to members of photographic societies, to aid in advancing the art. We should like to see every man with ability, or opportunity to do so, to take a speciality and master it. Let each one pursue the general practice of the art as duty or inclination may dictate; but let each one, in addition to this, take up a special subject in which to excel and become a master, and resolve to produce, say at least once a year, in time for the exhibitions, the very best specimen of that branch of which he is capable. Let them adopt, in regard to such speciality, the example of Mr. Robinson, of Cheltenham. He has adopted, as his especial aim, the production of artistic pictures by combination printing. He is engaged very closely in the active practice of his profession of portraiture; but in addition to that, one or more composition pictures have to be produced every year, as his direct contribution to the art progress of photography. Let each photographer adopt this principle of producing something yearly for the advancement of the art. There are many branches open: instantaneous photography, architectural photography, marine photography, the production of clouds and atmospheric effects, the production of foliage, flowers, and ferns, photographing animals, photographing specimens of various branches of natural history, microscopic photography, reproductions, enlargements, artistic and fancy printing, art studies, photolithography, carbon printing, &c. If every capable and enthusiastic photographer would systematize and give definite purpose to his effort, by adding to his general practice a special aim, and then exhibit his results and describe his methods, an impetus would be given to the art, and a beauty to its productions not hitherto obtained.

SAVING THE SILVER.

A REFINER in the United States has hit upon an ingenious idea to facilitate the preservation of a large proportion of the precious metal used by photographers, from waste and entire loss. He proposes to furnish to each photographer, and attach to the sink in his operating room, free of cost, an apparatus for reducing the silver contained in the water usually wasted by running down the sink into the sewers. At stated intervals the deposited residue will be removed

and reduced to the metallic state, three-fourths of its value will then be returned to the photographer, one-fourth being retained by the refiner for his share of the transaction. Here is the advertisement of the projector:—

SHAW'S APPARATUS FOR SAVING SILVER AND GOLD FROM WASTE SOLUTIONS.

According to many experiments made on this side of the Atlantic, as well as in Europe, to ascertain the amount of silver contained in *photographs, negatives, &c.*, it is found that a very large proportion of all the silver used is actually thrown away and lost, three quarters being the lowest estimate made of the amount thus wasted. Experience has taught that a large proportion of this useless waste of the *precious metal can be saved* by the use of the above apparatus, which has been in successful operation for the past year with good results. And I propose to put it in the hands of every photographer in the United States upon such terms as shall be practically without cost. I, therefore, propose to furnish the apparatus to every one applying for it, *free of expense*, who will set it up and follow the instructions for using it (which are very simple), upon the following terms:—

If I refine only such waste as the apparatus saves—hitherto a dead loss—I will return half the amount without cost of refining, my proportion to pay for rent of apparatus, use of patent, &c.

If, however, the operator will deliver to me *all scrap and waste* he can save by following my directions, I will refine it without cost and return three-fourths, retaining one-fourth for services, &c., as mentioned above.

By the last method I can return *MORE MONEY* to parties using my patent than they can possibly realize by saving in any other manner, even if they could refine the waste for nothing, as my invention will save a much larger per centage. My object in making this liberal offer is to remove all temptation to infringe my patent.

To carry out this plan, and at the same time to assure parties that they will be perfectly secure respecting their just share of the amount so recovered, I have associated myself with a *responsible party* well known to a large proportion of the photographers throughout the United States.

We commend the idea to some enterprising firm in this country.

PHOTOGRAPHIC CHEMICALS:

THEIR MANUFACTURE, ADULTERATION, AND ANALYSIS.

Zinc (continued).—Chloride of zinc is extremely deliquescent. When in the state of aqueous solution it is very valuable in the laboratory for small soldering operations. When soldering has to be frequently performed, it is convenient to employ a "soldering bolt," or "iron," which "iron" consists of a heavy lump of *copper* rivetted between two pieces of iron, ending in a rod of the latter metal firmly fixed in a wooden handle. The head is cleaned with sand paper, heated to a little above the melting point of solder, and then dipped into a strong solution of chloride of zinc. The solder is then rubbed on it, and it will be found to run over the whole surface instantly, the melted alloy *wetting* the copper as water will wet wood. In soldering any two pieces of metal together, the surfaces which are to be in contact are, first of all, well cleaned with a file, and then wetted with solution of chloride of zinc, or soldering fluid, as it is more frequently called. The soldering bolt is now heated, a globule of solder taken up by its point, and rubbed along the joint. The heat of the bolt will be sufficient to heat the surface of the metal, over which it is rubbed, to the melting point of solder, which will run along the joint and make it perfectly fast. For small laboratory operations, a soldering bolt is not generally necessary. Suppose, for instance, it is required to solder two pieces of tin plate together, it is merely necessary to place a few drops of the soldering fluid on the clean surface to be joined with a small scrap of solder, and hold them on a slip of wire gauze over a spirit lamp. As soon as the water has boiled away, and the residue of chloride of zinc has fused, the solder will melt and run evenly over the surface. The same thing is now to be done with the other piece of metal, care being taken in each case to limit the surface covered by the solder to those portions which are to be in contact. Upon now placing the two soldered surfaces in contact, and heating them for a few moments over the spirit lamp, the alloy will melt and unite the two together. Before they cool, the two pieces of metal should be firmly pressed in contact, and the excess of melted solder may, if desired, be wiped off while still liquid, with a cloth. When cold, the chloride of zinc must be well washed off.

Some persons recommend the addition of hydrochloric

acid, or chloride of ammonium, to soldering fluids, but we do not think anything is better than simple chloride of zinc.

Chloride of zinc will unite with chloride of ammonium, forming a double salt. A solution of equal atoms of chloride of zinc and chloride of ammonium being evaporated together in the presence of a little hydrochloric acid—added to replace the acid which may escape during the evaporation—yields, on cooling, transparent prisms which are permanent in dry, but deliquescent in moist, air. The crystals contain one atom of water of crystallization, and dissolve in less than their own weight of cold water.

Nitrate of zinc is of interest, as being the first substance applied to an excited collodion plate for the purpose of preserving its sensitiveness longer than a few minutes. By dissolving metallic zinc in nitric acid, there is formed, together with nitrate of zinc, a small quantity of nitrate of ammonia, which arises from the deoxidation of the nitric acid by the zinc and the union of the remaining nitrogen with hydrogen from the decomposition of the water. It is probable that the partial want of success experienced by some who followed Messrs. Spiller and Crookes' original process of preserving the sensitiveness of collodion plates, may be attributed to the presence of this salt of ammonia. The best way to prepare nitrate of zinc absolutely pure, is the following:—Take pure oxide of zinc prepared by precipitation, with the precautions mentioned in the last chapter on this subject, and dissolve it in nitric acid, taking care that the latter is in decided excess; now evaporate on a water bath until the solution is of a syrupy consistency, and allow it to cool. Nitrate of zinc will crystallize out in transparent, colourless, four-sided prisms. Separate these from the mother liquor by draining, and re-dissolve in water. Now evaporate again on the water-bath, and continue the evaporation until the salt appears dry, stirring it about constantly with a glass rod. The crystallized nitrate of zinc contains six atoms of water. When heated, it fuses, and at the temperature of the water-bath three atoms of water are evolved. The salt dried as above directed, contains therefore three atoms of water. Nitrate of zinc is very deliquescent, and is likewise soluble in alcohol.

Oxide of zinc dissolves in potash, and partly on that account metallic zinc will dissolve in the same liquid. When the zinc is free from any other metal, it dissolves very slowly, but when platinum or iron—preferably the latter—is in contact with it, hydrogen is evolved with some rapidity, and the metal quickly dissolves. The hydrogen gas so obtained is of value in many operations, as it is free from the sulphur and metallic impurities so frequently present in hydrogen gas obtained by dissolving zinc in dilute acids.

Cadmium is a metal which possesses many compounds of use in photography, especially the iodide and bromide. The metal itself is very similar to zinc in its chemical properties, and is generally found in ores of the latter metal. It is a white metal with a strong lustre, and intermediate in colour between tin and zinc. It has a dense texture, is soft, but harder and more coherent than tin; is easily cut with a knife, very flexible, and easily beaten out into thin plates, or drawn into wires. Its specific gravity is about 8.7, it fuses below a red heat, and volatilizes at a somewhat higher temperature. Commercial cadmium is very liable to be contaminated with zinc, for, being prepared by a rough manufacturing process from residues which contain a large per centage of the more common metal, it is not easy to effect the separation of the two with chemical accuracy. The best means of separating zinc from cadmium is to dissolve the metal in dilute sulphuric acid, taking care that the acid is present in considerable excess, and then to pass sulphuretted hydrogen through the acid solution. This precipitates all the cadmium as sulphide, whilst the whole of the zinc remains in solution. It is then filtered, and the sulphide of cadmium washed with plenty of water. It is then dissolved in dilute nitric acid, and the solution evaporated to dryness. The residue is dissolved in dilute hydro-

chloric acid, taking care to have as little excess of the acid as possible, and to the clear liquid, strips of pure metallic zinc are added. These precipitate the pure cadmium, as a spongy mass, which must be collected together, washed quickly, and fused in a crucible, under tallow or cyanide of potassium.

If the cadmium is required in the form of iodide or bromide, or similar salt, it is not worth while to reduce it to the metallic state, as much trouble may be saved by converting it into oxide. This may be prepared from the solution of the precipitated sulphide of cadmium in nitric acid. The filtered liquid is to be diluted with water and an excess of caustic potash added. This precipitates the cadmium in the form of hydrated oxide, which must be filtered, well washed with water, and dried at the temperature of boiling water. In this state oxide of cadmium is a fine white powder, containing one atom of water, which it loses at a red heat. It dissolves readily in acids, forming salts.

Sulphide of cadmium is largely used as a pigment, being of a very brilliant orange yellow colour. It is precipitated in flakes by adding hydrosulphuric acid, or sulphide of ammonium to a solution of a cadmium salt. It may be prepared of slightly different shades of colour, by varying the concentration of the solution and the temperature at which the precipitation is effected. The dry sulphide darkens in colour when heated, becoming first brownish, and when at a red heat, carmine red. It may be prepared in the dry way by igniting oxide of cadmium with sulphur, and then possesses a somewhat darker orange tint. It is not volatile at any temperature, but at a white heat fuses, and on cooling solidifies to a transparent lemon yellow crystalline mass. Sulphide of cadmium is very valuable as a pigment, owing to its unalterability under ordinary atmospheric agencies. Being already a sulphide, it is of course not attacked by sulphuretted hydrogen, and having no tendency to absorb oxygen under the influence of light or moisture, it is as near an approach to an absolutely permanent colour as the artist can hope to obtain. We are not, however, quite certain that it would be a safe colour to mix with tints which are altered by sulphur, as it is not unlikely that under these circumstances a double decomposition might take place in course of time, and some of the sulphur might leave the cadmium and go where it could commit havoc among the delicate shades.

RESEARCHES ON POSITIVE PRINTING.

BY MM. DAVANNE AND GIRARD.

TONING.

1. *Definitions*—In photography, the operation to which the name of *toning* is given has for its object the changing the hue of the positive proof, so as to place it in the best possible conditions of stability, and, at the same time, to impart to it an agreeable tint.

To obtain this result, the operator takes the proof either fixed in hyposulphite of soda, or simply washed on being removed from the printing frame, while still impregnated with all the insoluble salts, which have not been reduced by light, and immerses it in various solutions, where, by special chemical reactions, the effect he desires will be realized.

These various solutions may, by their very nature, be placed in two very distinct categories. In the first figures the salts, or even some imperfectly defined compounds, intended to act upon the silver in the proof, and change the original hue by a modification in the condition of that metal; these are the baths known under the name of *old hyposulphite, acidulated hyposulphite and hyposulphite charged with salts of silver*. In the second figure only the solutions of metals more electro-negative than silver, almost always gold, sometimes, but rarely, platinum.

We should examine successively, and from the two different points of view which the question of these two classes of solutions admits of, if our previous researches had not led us to reject the first absolutely, and to refuse to admit modified hyposulphites as toning agents. The cause of this rejection is also easily comprehended; according to our definition, the toning

agent must satisfy two *desiderata*: to produce upon the proof a colour agreeable to the eye, and to place the image in the greatest possible condition of permanency. Now, if, as in fact does take place, these toning agents can impart the agreeable hue to the proof so long sought for, and if, consequently, they satisfy the first *desideratum*, they are very far from satisfying the second. We have very clearly proved, in fact, both in the *general study of positive proofs*, and in a *mémoire* presented to the French Photographie Society, 19th of October, 1855, that all these solutions, far from placing the proofs in conditions of stability, always introduce sulphur, inevitably, that agent of destruction so much dreaded by the photographer. These solutions, then, must be wholly rejected for toning: they are so now almost generally; the cautions we gave have borne their fruit, and it is very satisfactory for us to see the efforts we have made to secure the permanency of positive proofs crowned with success. We shall therefore not dwell upon the processes connected with this class of solutions; they belong to the photography of the past; moreover, since the *Mémoire* of 1855, referred to above, we have carefully watched their mode of action.

Here we confine ourselves solely to the study of the various solutions of gold, and sometimes of platinum, employed by photographers for toning. Do they satisfy the two conditions required by our definition? Do they give, and under what conditions do they give, agreeable hues? Do they introduce into the substance of the proof any compound of a nature calculated to effect an alteration? These are the two questions which must be solved, the one by the practical photographer, the other by the analytical chemist. But before describing the solution, we must endeavour to render an account of the chemical nature of the reactions which take place during toning; in a word, describe the theory of this operation; certain that in the course of this inquiry the remaining facts will present themselves and furnish us with the elements necessary to resolve the two questions proposed.

2. *Theory of toning*.—As well as chemical theory will permit us to foresee, it is by a simple operation of substitution that toning is effected; a portion of gold is deposited, a portion of silver is dissolved, and gives place to the gold; it is the same when toning takes place by means of solutions of platinum. The result is the same whatever the conditions; whether the paper be sized or not, the toning bath acid, neutral or alkaline; whether the toning takes place before fixing or after, gold is always deposited. Doubtless, remarkable differences present themselves according to circumstances, but we have not taken these differences into account for a moment, but confining ourselves to the general fact, we say, in toning a portion of the silver disappears, and is replaced by gold or platinum.

The proportion of metal thus deposited is very regular in quantity; it varies a little, it is true, with the intensity of the proof, the time of toning, &c., but in the ordinary conditions of photographic operations, it maintains a proportion between the fourth and the fifth of the quantity of silver in the proof. This is shown by the following example arising from the analysis of photographic proofs toned with chloride of gold.

Silver	2.28 grains
Gold	0.43 "

It is the same with proofs toned with platinum, as shown by the following numbers:—

Silver	0.96 grains
Platinum	0.25 "

In the first case the proportion is about one-fifth, in the second it a little exceeds one-fourth.

This proportion, which we have very often verified, varies a little, as we have before stated, from different causes, and especially, as might be foreseen, with the time during which the proof remains in the toning bath. Still, the increase in the weight of gold never surpasses certain limits, the substitution of the gold for the silver must never be complete: in a word, the silver must never entirely disappear from the proof. The contrary opinion has been announced lately by Dr. Schnauss, of Jéna, who assumes the possibility of an absolute substitution, but this opinion rests upon an error in analysis: we have had occasion to dispute it, and must now recur to it. Let us first relate the experiments upon which our conviction is based; in order to free the operation from all accessory circumstances, these experiments were made upon paper simply salted, and the toning

took place only after complete fixing; so that in the event of a certain portion of silver remaining on the proof after toning, it could not be attributed either to the presence of albumen, or to non-impressed insoluble compounds, but to some other cause. The papers, well fixed and washed, were introduced into the gold toning bath, and kept there for *thirty hours*, frequently renewing the bath, in the fear that if it became weakened, the toning would not proceed so freely. These papers fixed anew, to remove the chloride of silver engendered during the substitution of the gold, and well washed, gave the following numbers upon analysis:—

Silver	0.38
Gold	1.14

These numbers are doubtless very different from those obtained under ordinary conditions; the gold is in much larger quantity, but still it has not replaced all the silver. Upon similar proofs not toned, analysis gave 1.80: the toned proof again contained 0.38, and we thus found ourselves led to conclude that the gold cannot remove all the silver, and that there always remains upon the toned proof about one-fourth or one-fifth of what it contained before toning.

In a theoretical point of view, there is nothing surprising in this result. In fact, the proof must be considered before being placed in the toning bath, as a simple plate of silver immersed in the bath, it presents two surfaces to it, the one in the pulp of the paper, the other on the surface of the paper; those two surfaces are gilded, and the silver is dissolved; but when the layer of gold has acquired a certain thickness, the middle part, placed between the two surfaces, cannot be reached, and remains undissolved. This result, which takes place every time a metallic plate is immersed in a gold solution, as for example, in wet gilding, is known to all chemists.

And it is solely from not having taken this fact into account that Dr. Schnauss has fallen into error. In his experiments, the proof prepared and toned under the same conditions as ours, was leicaterated, and the ashes submitted to the action of nitric acid, which, according to Dr. Schuauus *ought* to have dissolved the silver, if the proof had contained any. There lies the error; a proof thus prepared may contain silver which the nitric acid will be powerless to dissolve. In fact, during the gilding a true alloy is formed between the surface of the gold and the surface of the metal which serves as a support to it; in the present case, this is an alloy of silver and gold; the proportion of gold is very considerable ($\frac{2}{3}$) and chemists know very well that alloys of this nature are not sensibly attackable by nitric acid. It is precisely to avoid falling into this error, that, in the numerous quantitative experiments we propose to describe, we have always taken care to appeal to inquantation, that is to say, bring the alloy into such conditions that the gold was not in greater quantity than a fourth of the silver.

After having thus established that the theory of toning rests upon a partial substitution of gold for silver, we have considered under what conditions this substitution takes place, and if it occurs in proportions required by the laws of equivalents. Here commences the great perplexity of the question, for the toning processes based upon the employment of salts of gold are numerous (we put aside the tonings with platinum, very rarely employed, and which act like the tonings with gold), and it is evident that the presence of the reagents added to the gold must considerably modify the results, and consequently influence the tone, intensity, and various other qualities of the proof.

(To be continued.)

ON THE BEHAVIOUR OF CHLORIDE, BROMIDE, AND IODIDE OF SILVER IN THE LIGHT, AND ON THE THEORY OF PHOTOGRAPHY.*

BY HERMANN VOGEL.†

I now pass to iodide of silver. I have already stated that this undergoes no visible alteration in the light. The question is whether any chemical change takes place, such as occurs with the chloride and bromide.

I first endeavoured to ascertain whether any iodine was set free. For this purpose I dropped freshly prepared thin starch

paste upon iodide of silver which had been long exposed to the light in a glass tube. No reaction took place. Nor could any evolution of iodine be observed during the exposure of iodide of silver covered with starch-paste to the most intense sunlight, and no free iodine could be detected with sulphuret of carbon. I repeated this test with starch-paste, containing iodide of potassium, which, according to Schöubein, is much more sensitive than pure starch-paste, but even with this no trace of free iodine could be detected.

From these experiments made under the most various conditions, I cannot but conclude that no iodine is set free by the action of light upon iodide of silver. Consequently, if iodide of silver undergoes a decomposition, this can only consist in the formation of *free silver*, or of a *subiodide*, and of a *superiodide*.

The formation of free silver can only be ascertained in this case by dissolving the undecomposed iodide of silver with hyposulphite of soda; by this means I obtained no residue of free silver. Free silver cannot be detected here by means of nitric acid, as iodide of silver is decomposed by that acid, both when boiled and when allowed to stand for a long time in the cold. The formation of free silver is, moreover, improbable, inasmuch as it must have betrayed itself by rendering the surface of a grey colour.

There consequently remains only the second supposition—that of the formation of a subiodide and of a superiodide. The production of the latter is, however, highly improbable. Even chlorine and bromine, although endowed with far stronger affinities, have but a slight tendency to form superchlorides and superbromides; still less shall we find this tendency in iodine. We know, for example, perchlorides of iron and copper, but no periodides of iron and copper in a free state. In experiments on the formation of such bodies protiodides alone are produced and iodine is set free.

Hence I cannot make up my mind to admit the formation of a superiodide of silver, and the less, as it is extremely improbable that, if it should exist, it could resist the action of iodide of potassium. But if no superiodide is formed and no iodine is set free, the formation of a subiodide or of metallic silver is likewise impossible. From these experiments and the views here developed, I am consequently led to the conclusion that *when iodide of silver is exposed to the light no chemical decomposition takes place*.

I have hitherto been describing the behaviour of haloid salts of silver which had been prepared by the agency of an *excess* of the precipitant (HCl, KBr, KI). *Somewhat different results are obtained by the employment of haloid salts precipitated by an excess of the silver salt*.

By this means the chloride, bromide, and iodide of silver are thrown down as caseous precipitates which are easily filtered and washed, whilst with an excess of iodide and bromide of potassium, the two latter, as already stated, form an extremely fine powder, which in part passes through the filter.

I prepared the above-mentioned three haloid salts by lamp-light, and washed them until the washing water no longer gave any silver reaction. I will indicate the haloid salts thus prepared as Ag Cl β , Ag Br β , and Ag I β , and those above described as Ag Cl α , Ag Br α , and Ag I α . Ag Cl β and Ag Br β do not differ from Ag Cl α and Ag Br α in external appearance, but Ag I β is decidedly a deeper yellow colour than Ag I α . The difference in the behaviour of the salts on exposure to light was more characteristic.

Ag Cl α is decomposed under the action of light more slowly than Ag Br α (*vide supra*); Ag Cl β , on the contrary, is decomposed in the light more rapidly than Ag Br β ; for if two tubes with Ag Cl β and Ag Br β and iodized starch-paper be placed simultaneously in the sunlight, the paper is always seen to acquire colour sooner in the tube with chloride than in that with bromide.

I ascribe the more rapid decomposition of Ag Br α , as compared with that of Ag Br β , to the finer division of the former, which is strikingly manifest even during its preparation.

As regards coloration, Ag Cl α and Ag Cl β , as also Ag Br α and Ag Br β , behave *exactly alike*. But the case is different with Ag I β ; for whilst Ag I α does not exhibit the least change of colour by exposure to light, Ag I β becomes decidedly grey, with a greenish tinge.

I now tried whether iodine is set free during the exposure of Ag I β . The experiments were made in the same way as those

* Continued from p. 532.

† Poggendorff's "Annalen."

* The original says Ag Br and Ag Cl β , but this is probably a misprint

above described with AgIa, and repeated many times, but I could not detect the least trace of periodine. In two experiments I noticed that after the exposure of the iodide in glass tubes for six hours, the iodized starch-paper enclosed with it was rendered slightly blue. But upon closer examination I found that the iodide employed contained a very small quantity of chloride of silver. From these experiments it is evident that neither AgIβ nor AgIα undergoes any decomposition by exposure to light.

ON THE COLLECTION OF RESIDUES OF SILVER AND GOLD IN PHOTOGRAPHIC ATELIERS.

BY DR. D. VAN MONCKHOVEN.

CHEMICAL analysis proves, that of every 100 grains of nitrate of silver employed in a photographic atelier, nearly 90 are found in the residues. We may therefore understand how important it is to collect as much as possible of these residues of silver, &c., and especially to collect them in such manner as to render their conversion into metallic silver easy.

Gold, now so generally employed for *toning* paper positives, is collected with much more difficulty from the residues, and its extraction is much less easy than that of silver; still, by operating in a suitable manner, we can recover a third of the gold found in old *toning* baths.

The *silver residues* are found:—

1st. In filters having served for silver baths; the bibulous papers employed for cleansing the frames of the camera; spoilt positives, &c. All these papers should be preserved in a large wooden box, and *when they are perfectly dry*, burnt to obtain their ashes. The best method consists in employing a well-cleaned iron pot, set over a clear fire, and placing a lighted candle beside it. The papers being opened, and lighted at the candle, are left to burn out in the pot until they leave a *white* ash, and *not black*, as would be the case if the papers were burnt *en masse*.

The ashes must be preserved in a bottle kept specially for the purpose.

2nd. *Old hyposulphites*. Throw them into a wooden cask,* which may be placed in a corner of a yard, or other open space. When it is full, throw in a solution of sulphide of potassium (liver of sulphur). Care must be taken to preserve this salt in glass stoppered bottles, else it gradually changes into hyposulphide of potassa, which does not precipitate the salts of silver. It is best to operate upon old hyposulphites only when a large quantity has accumulated.

It is necessary to be careful and not add an excess of sulphide of potassium. To avoid this risk, the following mode of testing may be followed. When the deposit in the cask has separated after the sulphide has been added, take a portion of the supernatant liquid, put it into a test glass, and add a few drops of the solution of the sulphide; it will then be easy to recognise if all the silver (and gold) have been precipitated. If the addition of a few drops of the sulphide produces no cloudiness, make a reverse test; take another sample of the liquid, and add a few drops of solution of silver to it; if a precipitate now takes place, it shows that too much of sulphide has been added, a fresh quantity of the fixing bath must then be added, and left to settle. These tests are necessary, for if sufficient sulphide has not been added, a portion of silver in the washings will not be precipitated, while, if too much be added, a portion of the precipitate is re-dissolved in the excess of sulphide, which causes a loss. But the latter defect is not so mischievous as the former.

A muddy precipitate is thus formed at the bottom of the cask which solidifies of itself in the course of a few days. Open the tap placed near the bottom of the cask, and allow the clear liquid to flow out. Add more old hyposulphite, and after repeating the operations several times, clean out the cask and throw the muddy precipitate upon a filter, and leave it to drain for several weeks.

Turn out the filter and put the black precipitate into porcelain dishes or upon plates of glass, and leave it to dry *completely* in a warm room.

3rd. Procure a cistern (mark it "*chloride of silver*") capable of holding forty or fifty gallons, larger at bottom than at top, and furnished, at four inches from the bottom, with a glass or wooden tap (not brass).

Pour into this cistern:—

A. Old silver baths.

B. The solutions which have served for washing the proofs before toning.

C. The metallic silver mud arising from the development of collodion negatives.*

D. The rinsings in washing dishes, &c., which have contained silver baths.

E. In a word, all the waters contain silver, except those containing cyanide or hyposulphite.

F. The *kaolin* used for clearing silver baths, which always retains a portion of silver. Collect it in a glass vessel, and add to it its volume of nitric acid mixed with water; let the mixture stand some hours, and then decant the liquid into the chloride of silver cistern.

When the cistern is nearly full, add some commercial muriatic acid (but no chloride of sodium, which dissolves a certain quantity of chloride of silver), stir it, an abundant white precipitate is formed, which is left to settle. Take a little of the clear supernatant liquid in a glass, and add a few drops of muriatic acid. If a precipitate is formed, it shows that sufficient muriatic acid has not been added to the cistern. Then add more acid, until, after being well stirred with a stick, and allowed to settle, a fresh quantity of acid added to the liquid produces no precipitate.

Leaving the whole quiet during a night, next day open the tap and allow the clear liquid to flow off. The silver deposit will be found at the bottom of the cistern. The operations of collecting the silver washings and precipitating by muriate may be repeated indefinitely.

When a convenient time arrives to extract the silver from the residues, throw what has been precipitated to the bottom of the cistern upon a filter, which may also be employed for the residues produced by precipitating old hyposulphites by sulphide of potassium, provided it has previously been cleaned. Leave the matter to drain for several days, then *dry it completely*, placing it in a warm room, either in plates or flat porcelain dishes.

It is absolutely necessary to completely dry all the residues before extracting the silver.

The chloride of silver, if it be pure and white, will yield 75 per cent. of its weight of silver; but if it is not completely dried, or if it contains foreign matters, it yields much less. Old papers, burned to a light grey ash, yield, on an average, 50 per cent. of silver.

The sulphides give less, because they often contain an excess of sulphur produced by the decomposition of the hyposulphite, or of the sulphide of potassium employed in their preparation.

Gold is extracted from *toning* baths in the following manner:—Throw into the bath—which most frequently is thick with a black powder of gold, slowly precipitated—some commercial muriatic acid, until the bath becomes of a decided yellow colour.

Take a filtered iron solution, formed of one part of sulphate of iron, dissolved in twenty parts of water, and pour it into the gold bath, to reduce it. The gold is precipitated immediately. Allow it to settle, decant the greater part of the liquid, which is thrown away, and collect the precipitate upon a paper filter placed in a funnel, shaking the dish and pouring the contents, precipitate and liquid, upon the filter.

Leave the filter to dry, cork it up in a bottle, and keep it to be reduced to the state of melted gold.—*Bulletin Belge de la Photographie.*

* This cask must be larger at the bottom than at the top, so that the precipitates may not adhere to the sides. At four inches from the bottom, pierce a hole, and insert a brass tap.

* Developing should be carried on over a gutta-percha trough communicating with the chloride of silver solution by means of a caoutchouc tube.

ON PHOTOGRAPHY IN INDIA.

BY W. H. WARNER.*

It is with a feeling of diffidence I come before you this evening to discuss the difficulties and trials which beset the path of the photographer (whether he be professional or not) in a far-off land—a land about which, what little is known photographically, has only lately been brought home to us by a few of those ardent amateurs who have been determined, notwithstanding all trials and troubles, to succeed—a land that teems with beautiful temples, constant and ever-varying foliage, and with people and animals that are interesting in themselves.

Having lately been occupied in printing large numbers of these very subjects for a celebrated amateur, they have led me to make many observations, which, without seeing the negatives themselves, I should never have had the opportunity of doing. In looking over these negatives, I observe in particular that great caution has been used in the opposing of that arch-enemy to the photographers of all countries—dust. I notice, secondly, that nearly every picture has been taken with what we in England would term "a long exposure;" in some instances I should imagine the exposure had been prolonged for fully three minutes. I observe, also, in some subjects, extreme detail, while in others of a similar character there is hardly any, although both have evidently received the same treatment as to manipulation. In nearly every case the negative has more or less suffered from what appears to be bad varnish: but which I have been assured was not so, it being the best Sohnée that could be procured. Lastly, that evil, which in Europe is bad enough, but in India is a million times worse—I mean heat—which dries up the plate, rendering it more and more insensitive every moment, and also communicates to the operator a lassitude which almost wholly unfits him for the duties of the day. These are some of the pleasures of photography in the East; pleasures, or rather vexations, which have bothered wiser heads than ours to overcome; and yet, looking at them fairly and steadily, I do not see but what they might be not only conquered, but actually made use of in the production of subjects. Let us, therefore, this evening discuss how these difficulties may be overcome.

What constitute the principal trials? *Dust* for one, I think; *heat* for the other. With the former, pinholes, comets, spots, and markings of all kinds appear, and mar the beauty of the picture. With the other insensitiveness, fringe-like markings, opaque spots, and reticulation of the film on drying, to say nothing of the minor evils of cameras splitting and letting the light through, glasses breaking, &c., &c., through the use of unseasoned materials. In looking more closely into the second item, viz., heat, we find that the exposure of the plate is considerably influenced thereby: dry heat tending to insensibility; damp heat to extreme—nay, excessive—sensitiveness. In India nearly all the clothes of the natives, and very many of the buildings, are white. These, with a glaring sun, in which the blue ray has little force, are very difficult to be properly rendered.

Now, as we cannot alter the heat and the light, let us see how we may obtain and keep for a lengthened period a sensitive surface which shall portray through a good lens with a small diaphragm every detail in the whitest possible dress or building, and how we may obviate and do away with the *dust* thus making photography a pleasure instead of a toil. The same remarks will apply equally to England in the taking of interiors and other subjects requiring long exposure.

In the sliding body of the camera, nearest to the plate, have inserted three thin strips of metal or wood stained black; this will form the bottom of the body into a tray. Have the same attached in a similar manner round the other

two sides and top. Then place in these trays a small piece of *spongio pilene*, dyed black for use, having dipped the *spongio* in water, and wrung it out until nearly dry. (In this stage it must be used when the sun has but little power; when very hot, use this almost wet.) Next, insert the same in the camera, and proceed to work as usual. You will observe that the *pilene* has one surface quite impervious to water; this is a non-conductor, which does not communicate its heat to the dampness of the other side, and, therefore, the inside of this portion of the camera remains perfectly damp without fogging the inner surface of the lens by a deposit of dew thereon.* It also forms an attraction to any particles of dust, be they small or large, and there they remain without the possibility of flying up on to the plate. Thus much for this, the *mechanical* portion of the subject. Having had a camera lately constructed upon this principle for a gentleman in the army, a pupil of mine, now *en route* for India, the makers, Messrs. Murray and Heath, will have much pleasure, I am sure, in showing those who may wish it a model of a camera constructed on the same plan.

Light, or the actinic force by which all pictures taken by the rays of the sun are formed, is, in my opinion, from what I have read and seen, but imperfectly understood in India, and, indeed, in many parts of our own country. Take, for instance, the usual run of large landscape pictures throughout England. Every operator has a different idea upon the subject of exposure: one considers it should be short, the other long; yet at the particular minute at which the picture was taken, there was *only one* proper time of exposure. How rarely do we see a picture perfect in every part; I am speaking generally. There are some gentlemen whose pictures always resemble the motto which accompanies Horniman's tea. Such are Wilson, England, Blanchard, Thompson, Bedford, Sedgfield, Breeze, Rejlander, and Robinson; but all these talented men will tell us that they, too, each and all, find a difficulty in deciding, at some time or another, what exposure to give certain pictures. They, too, have their failures along with others.

If, therefore, this is the state of things here, how much more difficult is it for the amateur to arrive at the proper exposure in a country like India? The climate, from all accounts, affects the human constitution more from its dryness than its dampness. In the wet season people are always healthier and better; photographic operations are generally successful then.—[*Vide* letter of Mr. S. Bourne, in *The British Journal*.]—Take, for example, a day in the hot season (4 a.m.), warm and light, cool air, thermometer at 75°. This is the pleasantest part of the day; the only time when photographs can be well got. Two hours later we have it 96°, and over 100°, till it reaches its maximum, during which period all out-door operations are at an end, except by the natives, whose craniums are well wrapped in white, to preserve them from the effects of the sun. As the day declines, a heavy dew succeeds, to be out in which is certain death. In the wet season, however, work may be done all day, in comfort and ease.

This summer, in England, we had, for a short time, a sample of what an Indian day is. I had letters from numerous gentlemen inland stating that they had found the same non-actinism of the light as myself, whilst others, at the sea-side, found no difference at all.

Then, again, in rainy weather—not foggy weather—the air is always clear; and though plates, when exposed, lose some portion of their charm from the lack of sunshine, yet there is a total absence of dust, spots, &c., &c., and the comfort of working is much increased. In India, the midday light is nearly all from the red and yellow ray, very little blue. Professional printers state that a negative may be exposed in the pressure frame until quite scorched, and yet be scarcely printed, while in the early morn and the wet season, a few

* Read at a meeting of the South London Photographic Society, Nov. 12th, 1863.

* The camera for India should be covered with canvas painted or stained black inside, and pure grey or white outside.

minutes suffice. The remark so aptly made by Mr. T. R. Williams this summer, that it was *the dryness of the atmosphere*, and *not* the light, was perfectly correct; and were we to carefully observe the various atmospheric changes, we should see that cold and damp induce to sensitiveness and rapidity of operation, while heat and dryness are the opposite. Dry and cold is good because it is clear and bright. Take, for instance, an October morning, or an April day—sun and showers. Contrast these with a hot sultry July and August day. Compare the results, and you will find in the one case points of light sparkling like diamonds here and there all over the plate, while the half-tone and the shadows have brilliancy and detail. In the other, although fine, there is a want—a something not easily definable, yet at the same time there.

I was much struck the other day with the force and truth of these observations. Being professionally engaged in illustrating a celebrated waterfall in South Wales, and having fallen in with what all would term “abominable weather”—damp and rainy to a degree—I found I could, with a compound lens well stopped down, get most exquisite effects, while on those days when we had the most brilliant sunshine and heat, the results were poor and meagre.

One day that I spent at the Abbey of Strata Florida, it rained (without fog), slightly all day, yet I got most exquisite pictures with moderate exposure. Another that I spent at Pontrhydyreos, brilliant and lovely though the scene looked to the eye, yet in the camera, the results were poor. I also compared the pictures of Bedford, taken in the winter with, I think, a single lens (Ross's), with those of Pumphry, taken in the summer with the same or a similar lens. In the former, there was detail and brilliancy; in the other, there was the lazy, snowy appearance so often got when the light and atmosphere appear to dance before one. Much, I admit, depends upon the manipulation in both cases. The proper management of the developer, its strength, &c., all help to form the whole; but without a correct appreciation of the quality, the intensity, and the quantity of the light—unless the correct, or nearly correct, exposure be given—the results will not be satisfactory. In India I am not in favour of using chemicals in extra quantities. A thirty-five grain bath made of pure recrystallized silver, such as supplied by Johnson and Matthey, of Hatton Garden, made slightly acid with acetic acid; a collodion formed of equal parts of Perry's bromo-iodized and Ponting's plain iodized mixed; developer of the strength of five, eight, to ten grains of iron to the ounce, according to the state of the atmosphere; the plate intensified by Blanchard's excellent formulæ (if necessary), *no pyro*, the Indian operator will be able to compete with his English brother, and work both with ease and comfort. Let the camera be fitted in the manner I have before stated, and the difficulties of Indian operations in photography will be materially lessened.

In conclusion, although I advocate dampness as opposed to dryness, still I do not entirely approve of the quantity of wet—“heavy wet” I may say—experienced since I have been in Wales.

Where the falls they roar, the streams they pour,
Forming cascades ne'er heard of before;
Where 'mid steaming vapours with thund'ring shocks,
The Welsh Niagara wears its rocks.

EXPERIMENT—PINHOLES.

A FEW days ago we took two stereoscopic negatives consecutively of the same object, with a pair of Harrison's globe lenses (of whose qualities we shall speak hereafter). The time of exposure in either case was ten seconds, and they were both developed with the iron solution and acetic acid, and were both equally vigorous and free from apertures after fixing. The first we intensified as follows:—The plate, whilst still moist, was flowed with a dilute solution of iodine in iodide of potassium, until the film assumed a slightly yellowish grey appearance all over; it was then well washed and flowed with two drachms of a solution of pyrogallie

acid, acetic acid, water, and nitrate of silver, in the following proportions;—

Pyrogallie acid	1½ grain
Acetic acid	1 drachm
Water	7 drachms

Nitrate of silver at the rate of 4 drops to each drachm.

After a while, as usual, the sky and other light parts become sufficiently intense for a negative. The plate was finally washed, dried, and varnished. It is free in a great measure from any decided imperfection.

The second plate we developed, fixed, and treated with a solution of iodine in iodide of potassium, in every respect the same as the first; and then, after washing, allowed the plate to dry. We afterwards varnished the edges and put it aside to dry. After a couple of days we immersed the plate in water, in order to moisten the film, and then treated it with the same intensifying solution as the first. As soon as the sky and other light parts were sufficiently vigorous, we washed the negative and examined it. It was speckled all over, and full of pinholes as well as holes of larger calibre. The negative is quite useless; it has got the measles or some other nameless dermatous eruption.

With the iodine treatment alone, the negative appeared almost intense enough. The colour at first was a yellowish grey, but it became bluish black in a day or two when exposed to the sun and diffused light, almost as black and intense as the first negative.

Photographers, draw your own conclusions; we are not prepared to draw any legitimate ones ourselves yet; we merely register the facts.—*Humphrey's Journal*

Hints to Operators.

A GOLD TONING PROCESS.

A CORRESPONDENT from whom we have at times received some exquisitely toned prints, in answer to our inquiry as to his toning process, sends us the following, accompanied by some stereographs, which are at once excellent in selection and manipulation. They will find a place at once in our selected gems. The tone is just that which we admire for landscape purposes. However valuable black tones may be occasionally in portraiture, we may remark here, that we think it is a great mistake to aim at black tones for landscape prints. The sentiment of many a lovely sunny landscape is spoiled by having black tones. These are a very beautiful, rich, deep brown, without the slightest approximation to redness or foxyness; but the deepest tone of warm sepia, a thoroughly sunny tone. As all the prints we have received are uniform in tone, we presume that with careful manipulation similar results may follow in other hands. It will be seen the carbonate of soda is used for neutralizing, and we presume the solution will not keep, but that it will be best mixed a short time before using.

Toning process.—In the first place dissolve half sovereign in

Nitric acid	1 drachm.
Hydrochloric acid	5 drachms.
Water	6 „

place this in a wide mouthed bottle with the coin on the hob, by the fire; it will dissolve in about 12 hours; when dissolved add sufficient water to make it up to 16 ounces, and label it *Solution Chloride of Gold*.

In another bottle make a saturated solution of carbonate of soda.

In another bottle, make a solution of common salt, 3 ounces to the pint.

Float your paper on a bottle of nitrate of silver, 90 grains to the ounce of water, or rather five ounces of water and one ounce of alcohol to the ounce of silver. I find that the alcohol keeps the solution colourless without the use of

kaolin. Print rather deep, and when your day's printing is complete, place the prints in a large dish of soft water and let them soak for half an hour, change the water once or twice, I need not tell you to save the water. While this is going on prepare your toning bath according to the number of prints; practice alone will determine how much, but, as an approximation, for about one gross stereoscopic take of

Solution chloride of gold	... 2 ounces
" of carbonate of soda	... 3 "
" of common salt	... 15 "

I may add that the cold weather is set in, I find it advisable to warm this solution, though in the summer, it tones so fast you can hardly manage it.

After well draining the water from the prints, place them in the toning bath one or two at a time, and when of the desired colour, place them in a dish of running water; when they are all toned, commence the fixing by placing them in a saturated solution of hyposulphite of soda for a quarter of an hour, then well wash.

CELESTIAL PHOTOGRAPHY.

At the October meeting of the New York Photographic Society, a paper was read, by Dr. Henry Draper, upon his arrangements for the photographic delineation of celestial objects. Dr. Draper said:—

"In the autumn of 1858, I determined to make the largest reflecting telescope in America. Its construction, together with the various improvements successively added, has occupied me, up to the present time, more than five years. The instrument, which is nearly sixteen inches in aperture, and thirteen feet in focal length, was intended to be devoted to celestial photography, and consequently contains many novelties especially fitting it for that purpose. A description of it was read at the Oxford meeting of the British Association, in 1860. It has since then been completed, and has now the largest silver reflector of any instrument in the world, except that in the Imperial Observatory at Paris. The Smithsonian Institute is preparing to publish shortly a full account of it, which will contain the entire detail of construction. The reflecting telescope is greatly superior to the achromatic for photographic purposes. In my instrument a movement of the sensitive plate, one-hundredth of an inch on either side of the true focus, visibly injures the image. In the great achromatic at Cambridge, on the contrary, the position of the plate may be varied over an inch without any noticeable change. The difference is simply that, while by reflection the visual and chemical rays both converge to the same focus, by refraction they do not. A sensitive plate, put where the eye sees the image sharply, produces a fine result in a reflecting telescope, but does not in an achromatic. Besides this, more light is reflected by a large silver mirror than an achromatic of equal size can transmit. At first I used speculum metal for my mirrors, but abandoned it at Sir John Herschel's suggestion in favour of silvered glass, the reflecting power of the latter being 93 per cent., while that of the former is at the best but 75 per cent. A large achromatic only transmits about 75 per cent. The glass mirror, too, weighs not more than one-eighth as much as the metal one—the one weighing 16 lbs., the other 128 lbs. It is also greatly more permanent, for if the silver coating which covers the glass concave should by chance be injured, it can be dissolved off easily with nitric acid, and the mirror resilvered in an afternoon, and this may be repeated indefinitely. A person making such a silvered glass reflector is content to take the greatest pains to produce a glass concave of the utmost perfection, for once that is obtained, it need never be lost. The thin sheet of silver deposited upon it, only 1-200000th of an inch thick, copies with the last degree of accuracy the glass beneath, and does not modify the figure of the surface, but only increases the reflecting power from two or three per cent. up to more than 90. This silver coating is transparent,

and shows bright objects, such as the sun, of a light blue tint, by transmitted light. The instrument has been in working order for eighteen months, but a large part of the time has been unused, because of my absence with the 12th Regiment, in Virginia, and on account of the duties of the Natural Science Professorship, in the University. With my father's (Professor J. W. Draper) assistance, I have, however, taken some very fine photographs during the past summer. Changes have been made in the photographic processes commonly used, in order to fit the pictures for bearing high magnifying powers. I have negatives which can be enlarged by a power of 32, without showing granulation or other effects to an offensive degree. The photograph which I show you to night is nearly two feet in diameter, and is magnified to 210 times the size of the moon as seen by the naked eye. It is the largest that has ever been made. I have now another, however, still larger in my observatory—nearly three feet in diameter—made under a power of 320. It represents the moon on a scale of 70 miles to the inch. In the picture before you attention should be directed particularly to the Appennine range, Copernicus (with his reflecting streams), the great groove from Tycho, the numerous craters, with an internal cone, the irregularities visible in the bottom of the Mare Imbrium. But it is useless to particularise; there is an almost inexhaustible supply of objects for study and admiration. The Society will see that, although celestial photography may be, as yet, only in its infancy, it is rapidly advancing. Every day is giving origin to improvements, and, even now, the limit of size in these pictures is rather owing to the great expense and difficulty of working such enormous plates, than to any intrinsic defect of the images to be copied."

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, November 12th, 1863.

SOME distracted penny-a-liner, at a loss for a new subject upon which to torture his pen, has revived the old hoax of the means of detecting a murderer by examining the retina of the victim, upon which, it is said, a picture of the murderer would be found impressed, and that if this were photographed immediately, it might, could, and would furnish a means of detecting the guilty. Perhaps it would, were it true, but it is one of those things we may be permitted to doubt, in the absence of ocular demonstration. In fact, I would not believe it were I to see it, having previously pronounced it impossible; and I think those who know anything of the cause of vision, and of photography also, will hold the same view as I do. However, a Dr. Sandford, of Boston, Massachusetts, has ventured to proclaim to the world that he has obtained a decisive proof of this remarkable *fact*. A certain Mr. Beardsley was murdered; thereupon, Dr. Sandford, in the interests of justice, and to the honour of photography, set to work. He began by dilating the pupil of the victim's eye, by means of a solution of belladonna; then the pupil, having been photographed, the picture was examined under the microscope, and exhibited the murderer—face, figure, clothes, and even the stones with which the murder was perpetrated.

Surely the doctor's imagination helped him a little, or he is inclined to amuse himself with the wonderful gullibility of the Boston *savants*. Our opinion remains the same—that it is all *mi-hi*.

The new session of the Photographic Society of Marseilles commenced with a meeting of the members on the 8th ulto. The chair was taken by M. Vidal, who remarked that the Photographic Society of Marseilles has taken an initiative and progress, which prove how strong the power of association is, which, without speaking of the resources and greater

influences, is seen in the emulation it excites, and in the clearness and development of the ideas which give rise to discussion.

During the present year, this Society, faithful to the programme it laid down, has actively pursued the study of dry collodion. Important works have been undertaken in this direction, and success has happily crowned the efforts of many members of the Society. The sensibility of dry collodion, however, leaves much to be desired, since the various processes communicated require from eight to ten times more exposure than wet collodion.

The constancy of the tannin process is not a sufficient advantage, we must contrive to give to this process a sensibility equal to that of wet collodion, and then photography will have made a great step in advance. There are three problems to which this Society has been devoted for the past two years, none of which have yet been resolved, notwithstanding the efforts and labours of a great many intelligent disciples of our art. These problems are—The permanence of positive proofs, the perfection of enlarged portraits, and instantaneous dry collodion; neither of these questions is yet satisfactorily solved in such manner as to render them legitimately the resource of practical photography, and yet the future of the heliographic art depends upon their complete solution.

In connection with this subject, M. Vidal entered into some technical details, and enumerated the successful attempts made by several members of the Society, foremost among whom are MM. Teissière and Jacquemet, whose labours are so well known in the scientific world. M. Jacquemet exhibited a caoutchouc dish entirely made with his own hands, and intended for washing dry collodion plates in.

It is well known to those who practise the tannin process, that before putting the tannin on to a sensitized plate, the latter must be submitted to as complete a washing as possible; we arrive at this with certainty by means of this dish and a stream of water, the jets of which are so arranged as to establish a current above and below between each plate.

It is a matter of regret and disappointment that photography does not occupy a more important position in the Exhibition of the Application of the Fine Arts to Manufactures, now open in the Champs Elysées. The fault is neither in photography nor photographers, but arises simply from the fact that the photographic exhibition is not a new one, but that which formed a portion of the *Salon*.

Among the most interesting specimens now first exhibited are some pages of a magnificent album in which M. Lafon has reproduced the whole of the *Campana* collection in the *Musée Napoleon III.* It consists of time-worn marbles, bronzes, enamels, terra-cottas, &c., with all the rust of antiquity upon them. The photographer's task was an immensely difficult one; but his success is complete. Two editions of the work will be issued; one costly, consisting of photographs, the other cheaper, by M. Poitevin's photolithographic process.

Exhibitors of manufactures have made good use of photography in giving representations of their inventions under a most satisfactory aspect to their customers; the draughtsman might mislead by exaggeration or imaginary perfections, photography being truth itself, and unimpeachable, is unhesitatingly accepted by the purchaser as a *fair* sample.

Photographic Notes and Queries.

PYROGALLIC ACID AND FORMIC ACID PRESERVATIVE.

DEAR SIR,—Having, the other day, a plate in my bath for which I had no further use, I took it out, washed it, then poured once on and off some old decomposed pyro and formic developer, and set aside to drain and dry.

After the lapse of some eight or ten days, I thought I would just try it for a transparency. So, giving it a second's exposure to day-light, and then a slight washing, I poured over some old

citric acid and iron developer, to which I added a few drops of nitrate of silver solution. To my surpriso, I got a much clearer picture than I had hitherto been able to obtain by the tannic formulae.

I regret not having much time for experimenting in an art at once beautiful and tantalizing; so, present gratis, if not forestalled, this hint for a new dry process to your thousand readers.—Yours, truly,

CORNISH CROUCH.

[Pyrogallie acid has been before suggested, and tried as a preservative, with more or less of success.—Ed.]

ELECTRIC LIGHT FOR PHOTOGRAPHY.

SIR,—In part reply to Mr. Busch's letter in your last, knowing a little of photography and a little about electricity, I once did print on a dry plate of some kind, so long since, that I forget what kind of plate. I had a very small induction coil, 2½ in. diameter, and 7 in. long, excited by three nitric acid iron cells, 3 in. diameter and 6 high. I used a condenser and attached the two ends of coil to the inner and outer coatings of Leyden jar, and then had a Lane's discharger, and adjusted the *nobs* to just striking distance; then by the flame between these *nobs*, I printed a stereoscopic plate. I moved it rapidly in front of the flame, and a few inches off, for about half a minute—the flame was about ½ inch. long.—I am Sir, yours truly,

W.N.B.

P.S. I should like to know where *cheap* apparatus are to be had.

OIL FOR TROUBLED WATER.

SIR,—It was said of old that the public functionary whom every one applauded could have very seldom done his duty.

Now, Sir, I hope I am not conceited, but it *is* gratifying to know that when recently playing the part of a public functionary in your pages it was not every one who applauded *me*.

But then, again, it *isn't* gratifying, because, my love of approbation is an extensive bump, and I am therefore sorry to find that at least two worthy and respectable married couples have been loudly indulging in very severe comments upon me as the writer of "A Dozen Hints to Portraitists," stating that the productions sold by the agent I described were their productions, and that consequently I therein dared to find fault with their work.

Permit me to assure both these manufacturers through your pages, that I neither know where the agent came from, nor who had produced the work he was engaged in vending.—Yours, &c.,

R. A. S.

Talk in the Studio.

NEW MEMBERS OF THE PHOTOGRAPHIC SOCIETY.—The following list of new members of the Photographic Society, duly elected at the last meeting, were accidentally omitted from the report in our last:—Messrs. T. Annan, Glasgow; T. B. Hutton, Guernsey; A. Harman, Peckham; H. Squire, King William Street; R. Faulmert, Woodlands, Lancashire; A. Wyatt, Fareham; A. Brothers, Manchester; V. Blanchard, Camden Cottages; W. Atkinson, Builth; F. Cooke, Tunbridge; John Eastham, Manchester; T. Lampray, Paternoster Row; Samuel Fry, Gracechurch Street; Athol Mayhew, Hart Street, W. C.; and Mrs. Spottiswoode, Phillimore Gardens.

COLOURED PHOTOGRAPHS.—We lately mentioned a dispute which had arisen between a M. Ricco, of Modena, and Colonel Baratti, director of the *Camera Oscura*, a photographic journal published at Milan, about priority of invention, both claiming to have found a method of producing photographs in the natural colours of the originals. We now find, from a number of the *Camera Oscura*, that the invention is far from being so important as was at first supposed; still it is worth describing as a decided improvement. Suppose it be required to colour the photograph of a man in a black coat, whose hair and beard are fair, and whose figure is projected on a white foreground, slightly shaded off. The process of the inventors is as follows:—The photograph taken by daylight lies in a basin full of water; it is dark, and the subsequent operations are performed by candle-light. Two solutions are at hand, one A, consisting of 1 gramme of chloride of gold and 10 of acetate of soda, dissolved in 1,000 grammes of water; the other B, consisting of 20 grammes of hyposulphate of soda, dissolved in

100 grammes of water. There are besides two more basins with water and a quire of blotting-paper. The photograph is taken out of the water, and put between the leaves of blotting-paper; it is then laid flat on a pane of glass, and the whole surface, except the face and hands, receives, with a water-colour brush, a coating of solution A. By this means the parts subjected to the action of the gold soon change their tints into black. The photograph is then put into clean water again, and left there for a few minutes, during which the operator prepares a second photograph if required. The former one being taken out, is put into solution B, where it stays for a few minutes, and is then washed and rinsed as usual. Now, as the time of immersion will influence the depth of colour, by successive immersions an orange-coloured cravat will be obtained in one minute, a coffee-coloured greatcoat, in five, violet-coloured trousers in ten, and a black coat in thirty minutes, while the hyposulphate of soda, or solution B, gives colour to the flesh and hair. Hence, certain colours, though not quite the natural ones, may be obtained, which is a decided step in advance.—*Galignani.*

PHOTOGRAPHIC PIRACY.—The London Stereoscopic and Photographic Company have just obtained another injunction with costs, which were heavy, against a vendor of piracies of their Exhibition photographs. A Mr. E. Watson, of Tottenham Court Road, was found to be selling largely pirated copies of the stereoscopic slides, printed as paper transparencies, at twopence each. These it appeared were imported from abroad, and were probably the production of Mr. Ceileur, who was before successfully proceeded against by the company for pirating similar works, and whose wholesale business in piracy has recently issued in bankruptcy and sudden disappearance.

To Correspondents.

**** PRESENTATION PRINT.**—We have pleasure in announcing to our readers that we have just completed arrangements for presenting to our subscribers, at an early date, a copy of Kenilworth Banqueting Hall, by the photo-electric engraving process of Mr. Duncan Dallas, from a negative by Mr. Francis Bedford. The print will be on tinted paper, the size of a page of the NEWS, from a plate untouched by the hands of the engraver. It is unquestionably the finest specimen of heliographic engraving which has ever been issued.

QUANTUM finds, in a recent formula, the phrase "6 grains of chloride of gold and sodium, containing 3 grains of chloride of gold?" he does not understand its meaning, and consults his friends. One says it means one thing, and another the contrary; but they all "agree that it is a careless and stupid way of describing the matter." He is equally at a loss as to the meaning of a "saturated solution" of anything. There is no great culpability attaching to "Quantum," or his friends, for being ignorant of the meaning of such phrases, but they are culpable when, being ignorant, they presume to characterize what they do not understand as careless or stupid. The salt to which Mr. Cooper referred is a regular article of commerce—a double salt of gold and sodium, two grains of which contain one grain of chloride of gold, so, prepared for the purpose of more readily securing an article without free acid. The term saturated solution suggests its own meaning. It is a solution in which as much of anything is dissolved as the liquid can hold in solution. For instance, bichloride of mercury is soluble in 16 parts of cold water; one ounce in 16 ounces of water will make a saturated solution, and if you add more it will remain undissolved. Bicarbonate of soda forms a saturated solution by adding 1 ounce to 10 ounces of water; chloride of sodium, by adding 1 ounce to 2½ of water, and so on; as much as can be dissolved forming, in all cases, a saturated solution.

C. BRYSON.—We prefer No. 2, and all we hear confirms this opinion.
STEPPING STONES.—The only danger you incur by using the droppings from the steam pipe in a factory is the possible contamination with organic matter, which sunning the bath will get rid of. You cannot very well colour a picture on albumenized paper, without slightly dulling the surface. The addition of dilute albumen to the colours has been recommended. We believe the tints or dyes sold for applying to photographs do not dull the surface.

BEAY.—The stains are probably caused by want of care in manipulating. The announcements of pictures registered, which appear in our pages, only refer to those sent to be registered by our publisher. It does not include any others.

JOHN MILTON.—A photograph must be registered before any copies are sold; but it does not matter how long it has been produced. You must fill up a descriptive form, and send it, with a copy of the picture, and Is. 3d. in stamps, to our publisher, who will then undertake the rest for you.

R. M.—It is probable that a salt of copper remained. It is not, however, we think, so important as some conceive to get rid of copper, or other metal, in preparing the chloride for your own use. It will do no harm if present, some believe that it will be even beneficial. 2. If you have not facilities for driving off the acids perfectly, you may keep the chloride in solution and neutralize when you require for use by means of chalk.

A. H.—A good copy of your print might, with great propriety, be sent to the Exhibition, and the stereos also; the cattle are especially interesting.

The entrance fee to the Photographic Society is one guinea, and the subscription a guinea a year. If you join now you will only pay subscription for the half year. We shall have pleasure in proposing you.

H. T. H. V.—Some plan of adjusting for focus at the back of the camera is decidedly desirable, and the travelling-screw answers very well. You may have the screw added to your camera without infringing any patent. 2. Instantaneous photography consists in securing a good negative by an exposure as short as can possibly be given, uncovering and covering the lens by the most rapid motion which can be applied. If your chemicals are in sufficiently good condition, your lens sufficiently rapid, and your light sufficiently bright, you may take portraits instantaneously. 3. The price of a glass-house may vary from £20 to a few hundred pounds; it entirely depends on size, style, &c. We do not know of one for sale. 4. The print enclosed is good for a beginner. 5. Uniformity of result can be secured by sufficient skill; as a beginner, you will fail at times; but skill will come with practice and perseverance. 6. For collodion the first you mention is excellent, and, so far as we know, the paper you are using is very good.

Y. Z.—If you had sent us a specimen of the defect to which you refer, we could better have understood its nature. It may arise from the drainings of the plate accumulating at the head, or from the developer not flowing evenly, or from the collodion being over-iodized, or some other cause, of which, without seeing the defect, we cannot speak.

S. JONES.—You may use either oxide of silver freshly precipitated or carbonate of soda for neutralizing the silver bath. If you use the former, take the freshly precipitated oxide (to make which we have often before described) and add to the solution with frequent agitation; after a few hours, filter. If you use carbonate of soda, take a 20-grain solution and drop a few drops at a time into the bath, agitating well between each addition. Each addition will cause a little turbidity at first, which will clear up again; continue adding until a slight permanent precipitate or turbidity is formed. It will now be quite neutral. Let it stand a few hours in the sun, and filter. 2. Throw down the silver in washing waters as a chloride, by the addition of common salt. 3. A tub may, with propriety, be used for containing it. 4. Burn paper clippings to ashes, and then put the ashes into the crucible with the flux. 5. If large quantities of touting solution be used, it may repay the trouble to obtain the gold from the effete solutions. Add protosulphate of iron, which will throw down the gold in a metallic state. Wash the precipitate well, and dissolve by means of *aqua regia*. 6. For mounting properly, glass shapes, a glass plate for cutting on, a sharp knife, fresh starch paste and a brush are required.

A. NOTICE.—In our opinion, A. decidedly. It is possible that you may meet with a genuine one, second-hand, from either of the dealers you name; whether you will save much or not, we cannot tell. The names you mention in your last list are many of them dealers, not makers, and the makers are not equal to the first mentioned.

ENQUIRER.—You will find the best information on the lime light in several articles on pages 13, 40, 74, and 136, in the fifth volume of the PHOTOGRAPHIC NEWS.

DEAFIA.—Your card is somewhat hard from over-intensifying. 2. After neutralizing an old bath it is desirable to sun it, and then add nitric acid very carefully, until it works clean. When it gets out of order again repeat the process.

T. COLLINS.—We prefer the first you name as possessing the qualities you require in the highest degree. We use it frequently. The last you name is good, but not so good as the first. We have no further decision regarding the Exchange Club at present.

PETER GRIFFITHS.—The metallic-looking stains are probably caused by hypo coming into contact with the prints before fixing, probably from handling with unclean fingers. There is no way to remove such stains, and the only way to avoid them is to use extreme care and cleanliness in working.

G. WILTON.—Your print is a little over-toned, but not quite sufficiently printed. Deep printing is required to secure deep tints. You require double the proportion of acetate of soda. The negative is pretty good.

CRAIOTS.—The Daguerreotype process was patented in this country in the year 1839, by Mr. Bevy, a patent agent for M. Daguerre. 2. In the same year it was ostensibly given to the world by the French Government, who pensioned Daguerre, in consideration of publishing his process. The patent was secured in this country, whilst the negotiations were pending with the French Government. This country was thus excluded from the gift, by what looks very like an underhand job. 3. Mr. Fox Talbot first announced his photographic discoveries to the Royal Society in 1839, and patented the process, with improvements, in 1841. 4. Some specimens of collodion positives were exhibited in the Exhibition of 1851. We have in our possession a collodion negative of the interior of the building.

A. GRANT.—The card pictures are a little hard; that of the lady is, however, a very pleasing photograph. Several Correspondents in our next.

CARD PORTRAITURE.

WE recently visited the establishment of Mr. T. R. Williams, to examine some improvements in his arrangements for the production of card portraits, which we propose to describe for the benefit our readers. We should remark at the outset, that amongst the cards we inspected were the most perfect examples of excellence in all photographic qualities we have ever met with. The vignette whole-plate heads of Mr. Williams have long been a standing illustration amongst photographers of all the most desirable qualities of portraiture. His recent card pictures have been in all respects of excellence the counterparts of the vignettes. Brilliant as it is possible for photographs to be, yet unsurpassingly delicate, soft, and full of tender gradations; wonderfully round and full of relief, and admirably defined at all points of the picture. The members of the Photographic Society, to whom Mr. Williams recently presented each a copy of their president's portrait, will at once recognize the union of many of the qualities of which we have spoken, in the charming picture they received; but it was by no means an isolated example, as many of the specimens to which we refer are still more perfect photographs. In mentioning the *recent* cards of Mr. Williams, we do not intend disparagement to his former pictures of this class; but, merely to emphasise the fact, that the recent productions are best, and that their excellence is due to various specific improvements.

The first improvement to which we shall refer is in the method of lighting. Mr. Williams' glass room is constructed, as it is with many metropolitan and other portraitists, in accordance rather with the necessities of the position, than with the design, which might, under other circumstances, be chosen. The light is derived chiefly from the top. The room is nearly square in shape, measuring about thirty feet each way. It has the usual ridge roof, which is dark or opaque on the slope at one side of the ridge, and glass at the other. The ridge is not, however, quite in the middle, the slope from the ridge to the eaves at one side extending further than the other, this side having the glass and facing the west. Adjoining the sky-light, there is also here a foot or two of glass in the front, but not reaching the ground by about eight feet.

The skylight is furnished with double sets of blinds, one set being blue and the other white. The blind rollers are placed at the highest part of the roof, so that the blinds may, by partial rolling up, be made to admit the light to any extent and at any angle which the position of the skylight permits. These blinds are in three divisions, any of which may be completely down whilst the rest are withdrawn. The background is placed underneath the opaque roof fronting the skylight.

If one of these blinds be withdrawn whilst the two others are down, it will be seen that a sitter placed under the latter will be illumined with what is practically a high side-light,

If two be withdrawn and one down, the sitter under the latter will be illumined with a high side-light and top-light. If all the blinds be withdrawn, or partially withdrawn, the sitter will be illumined with a front and top light. The varieties of lighting afforded by these arrangements were found to answer admirably for the production of large portraits. By keeping one or more of the blinds quite down, with the sitter under it, whilst the other blind was quite withdrawn, sufficient side-light effect was secured, and by turning the head the flattening effect of front light was avoided, whilst the amount of diffused light gave texture and softness, and carried detail into the shadows.

This method of lighting, which answered so well for large head was not found so successful in card pictures. The exigencies of position in portraying full-length figures often compelled the use of front light, and in attempting to overcome the flatness, a tendency to hardness resulted which was difficult to avoid. The presence of diffused light, which in large heads gave softness, in cards had a tendency to destroy relief and produce weakness. By the skilful management of chemical conditions it was possible to avoid allowing these tendencies to prevail in any exaggerated degree, but still the pictures so produced did not possess the qualities which had given such a pre-eminence to the vignettes.

By an entire re-arrangement of the position of various objects, however, it was found possible to secure the conditions of lighting which would give to card portraits the qualities which distinguished the others, and produce the charming pictures to which we have referred. This is effected by placing the sitter and camera at opposite corners of the room, thus altogether changing the relation of the light to the sitter. The background, &c., instead of being parallel with the front light, is placed cross-corner wise, and the camera at the opposite diagonal corner. The high front-light is thus converted into a high side-light, and more complete power in obtaining a direct light, from an angle largely under control, is secured. Instead of relieving the shadows by diffused light, it is largely dispensed with, and reflected lights are produced by a screen covered with blue calico placed at a suitable angle. The effect of this direct light is to give bold and well relieved contours, whilst there is sufficient of reflected light, and what the late Mr. Lacy used to call glancing light, to give texture and softness. The direct light has another advantage; it causes the figure to cast a soft shadow on the background, which is of immense value in giving relief and preventing the inlaid effect sometimes seen when the figure stands against a spotless, plain background unrelieved by light or shadow. If those of our readers who have glass rooms constructed in a manner similar to that of Mr. Williams will try the experiment of working in the direction to which we have just referred, they will readily perceive the increased control they obtain over the direction and concentration of the light.

In order to work from either corner of the room, as the state of the light or the desired position of the sitter may render necessary, there is a background in each corner. In

connection with these there are some other improvements. The backgrounds are not moveable, but fixed in their position. At each end of each screen is another movable screen placed at right angles, one at the end next the light for regulating the light and shadow on the background, the other, covered with blue, for regulating, by reflections, the shadow on the face. To avoid showing a head-rest, which sometimes appears in a very unsightly manner behind standing male figures, Mr. Williams has had a very clever contrivance constructed. Behind the background a base, carrying a firm pillar, is screwed to the ground. At the top of the pillar, which is about two feet or thirty inches high, is a V groove in which slides a stout wedge-shaped bar, which can, by means of a clamping screw, be fixed at any point. This bar projects through a small aperture in the background, and carries another pillar in front of the screen, to which is attached the head-rest, which possesses universal joints, permitting it to be moved in any direction. It also carries a rest for the back, which is of infinite value in supporting standing figures, giving the utmost ease in pose, and affording almost absolute security against the sitter moving. It will readily be seen that by this contrivance the sitter has the best possible aid to perfect and motionless ease and tranquillity, without any awkward head-rest being seen, or unmeaning mass of drapery being thrown about the feet to hide it. The sitter must, of course, be placed somewhere near the right position in relation to the rest, to begin with, but the universal joints admit of sufficient adjustment to prevent the stiffness which would ensue if the sitter had to accommodate himself to a fixed and rigid rest. As will readily be seen, all the parts of the rest must be firmly made and fitted to secure sufficient firmness and rigidity of support.

The height and position of the camera, which are of more importance than is thought by some, receive careful consideration. They must vary of course with circumstances; but for standing figures of medium height the following relations are preserved. The floor being level, and no platform used, the distance from the floor to the centre of the lens is about forty-six or forty-eight inches, which brings the lens about opposite the chest of the model. This, for giving equality of definition to the whole figure, is rather too high; but if the lens were placed lower, an unnatural and inartistic view of the face would be obtained, the under portion of the features being rendered as though the observer were looking upwards at them, a most displeasing effect. To compensate, in definition, for placing the lens a little above the centre of the model, the rising front of the camera is raised about one-fourth of an inch, and the camera very slightly tilted, so that the central pencils are chiefly used in defining the figure; the camera being of course made so that under ordinary circumstances the plate and lens should occupy their usual central position. The camera is only very slightly tilted, just sufficiently to gain an advantage without any perceptible disturbance of perspective resulting.

This arrangement with the card lens used—Dallmeyer's No. 2 B—gives excellent definition to all parts of the figure with open aperture, and the most perfect definition that can be desired with a central stop of $2\frac{1}{4}$ inches diameter, which is the smallest aperture Mr. Williams ever uses. The focus is not necessarily obtained on the eye, but frequently on some prominent object on the chest: this being sharp, the lens has sufficient depth to give not only the face, but the hands, feet, accessories, and all parts of the picture in satisfactory definition. A focussing eye-piece is always used to obtain certainty in focussing. With the stop, the exposure is in summer from two to five seconds, and with open aperture nearly instantaneous. In winter the longest exposures given are from fifteen to twenty seconds. If negatives are not obtained with this exposure, the light is considered so bad that sitters are declined.

Mr. Williams does not use scenic backgrounds; the screens are painted, in flattening a warm grey of medium tint.

A variety of carved oak accessories, such as tables, cabinets, bookcases, flower stands, &c., are occasionally introduced; and sometimes a curtain; the camera, &c., are surrounded by a small dark room, to prevent as much as possible diffused light from entering and spoiling the brilliancy of the picture. One lens is used, and a back with three repeats, taking three portraits in succession on a whole plate, a size which leaves ample margin for working with comfort.

Bromo-iodized collodion, by various makers, is used. A thirty-grain silver bath, as nearly neutral as possible. An iron developer containing about fifteen grains of the proto-sulphate and fifteen minims of acetic acid to an ounce of water. The exposure is always so full that the development is rapid, and the plate is washed before the slightest trace of deposit has had time to form on the deepest shadows, the negatives always presenting some points of bare glass. They are fixed in hyposulphite of soda, and then, after thoroughly washing, are intensified with the usual solution of pyrogallie acid, acetic acid, and a few drops of fresh nitrate solution. The negatives thus obtained, although exceedingly brilliant, print very rapidly in the shade, sun printing being generally avoided.

A moderately strong printing-bath, strength depending on the paper used. For very thin negatives, a paper containing a very small proportion of salt to the albumen. A toning bath of chloride of gold and acetate of soda made always a week in advance, but never used twice. A fixing bath of hyposulphite of soda, one part in six of water, never used twice. Washing for four hours in rapid changes of water. These, with the utmost care and delicacy used at every stage, produce the charming pictures we have described, which, as examples of exquisitely perfect photography, we believe, are not surpassed in the world.

Scientific Gossip.

SILICON, A NEW COMPOUND SENSITIVE TO LIGHT—LEUKON.

The photographic action of light upon all matter was some time ago a favourite subject of discussion and experiment. The researches of Herschel, Hunt, and others went far to prove that the chemical change which light was capable of inducing upon mineral and vegetable bodies was not confined to a few substances only, but extended generally to a vast number of substances in each class. Probably chemists would find this subtle agent much more generally active than they have hitherto suspected it to be, were it not that, from the fact of their almost always working with apparatus and reagents bathed in a sea of light, the changes or modifications produced by this force are unnoticed by being merged into and confounded with those obtained by ordinary chemical force. If it is desired to ascertain the action of moisture upon any compound, it would clearly be inadmissible to perform all the operations in an atmosphere saturated with aqueous vapour, and it is equally impossible to notice the chemical action of light on a body when both it and the reagents which act upon it are constantly kept in the light. Some few notable instances, it is true, have been observed by experimentalists, and precautions are consequently always taken to prevent photogenic change; thus in preparing silver salts of organic acids, care is taken to avoid exposing them to the action of light, and in some few other instances, similar precautions are recommended; it is also known that some dyes are only to be obtained in perfection on a bright sunny day; but putting these instances on one side, we may say that the already known photographically sensitive bodies are very small and not one-tenth of the number which might be discovered if proper steps were taken to isolate the action of light from other interfering causes.

The addition of a new member to a class of bodies is always of interest, but the discovery of a new and very sensitive photographic body is of especial value, more particularly, if entirely new ground is opened out by it, and

the stranger comes before us as the representative of a new series of elementary bodies hitherto unsuspected of the slightest tendency to photographic change. If we had had to hazard a prediction as to the body whence the next photographically sensitive compound would be derived certainly the last substance which would have suggested itself would have been common flint, or silica. Until the last few years, silicium, the basis of this, was about the most uninteresting substance in chemistry, but now, through the researches of Wöhler, it bids fair to rival any of the other elements in the number and interest of its compounds. This chemist has recently discovered several new compounds of silicium which are of the highest importance. The starting point of them all is a curious, metallic-looking alloy of silicium and calcium, which is easily prepared by fusing together silicium, chloride of calcium, and sodium, with certain precautions. The silicide of calcium is then obtained in a button of a lead grey colour and perfect metallic lustre. In water this slowly disintegrates, forming a mass of lustrous scales like graphite, some impurities being extracted from it by this solvent. Strong nitric acid does not attack the silicide, and this acid affords the best means of obtaining it free from impurities. The most remarkable action of the silicide of calcium is its behaviour with hydrochloric acid, by which it is changed into an orange-yellow substance, a brisk evolution of hydrogen taking place. This yellow body is called by the discoverer *silicon*, an inappropriate name, we may state *en passant*, as the metallic basis of silica, *silicium*, is often called silicon, and is generally known under that name in chemical books. Silicon is prepared in the following way:—The silicide of calcium, purified as above, is treated with concentrated hydrochloric acid in a vessel which must be placed in cold water to prevent the heating of the mixture. An evolution of hydrogen soon takes place, and the silicide is gradually transformed into silicon. The mixture must be often stirred to bring the powder entangled in the froth in contact with the acid, and then left for some hours in a dark place until the evolution of gas has ceased. It is then diluted with six or eight times its volume of water, the silicon filtered off, carefully protected from the light, well washed, then pressed between bibulous paper, and finally dried in a vacuum over sulphuric acid, the bell glass being covered with a black cloth. Silicon is of a bright orange-yellow colour. It is composed of transparent yellow laminae. It is insoluble in water, alcohol, and other solvents; when heated it becomes of a dark orange yellow. On applying a stronger heat it takes fire with a faint deflagration and some sparkling, leaving a residue of silicic acid.

The behaviour of silicon when exposed to the light is very remarkable. In the dark, even when moist, it remains quite unchanged. In diffused light it becomes paler; but in direct sunlight it, in a short time, becomes perfectly white, and hydrogen is given off. When placed under water in sunlight, hydrogen begins to be evolved immediately, and continues like a fermentation until the silicon has become quite white. The purer the substance the more quickly does the change take place, and several grammes are transformed in a few hours. If, however, it has not been perfectly protected from the light in the course of preparation, it is much longer before the whole is altered in sunlight. The formula of silicon is not accurately settled; but it contains silicium, hydrogen, and oxygen, and is supposed to resemble an organic body, in which silicium replaces the carbon. Professor Wöhler, indeed, suggests that it may, perhaps, be the type of an entire series of similar bodies, and it would then open the prospect of a special chemistry of silicium as of carbon. When we remember Dr. Hofmann's celebrated definition of organic chemistry—"a history of the migrations of carbon"—and think what a vast subject that now is—a science of itself almost too vast for one mind to grapple with—we may well feel interested at the prospect opened out to us, of a new science having silicium for its basis.

The behaviour of silicon with metallic salts is curious. In the presence of an alkali, even of dilute ammonia, it is gradually changed into silicic acid, with evolution of hydrogen. When mixed with an alkali, whilst this decomposition is going forward, it acts as a powerful reducing agent on the salts of the heavy metals. Solutions of copper or silver salts soon become black, and gold solutions brown. From solutions of chloride of palladium and osmic acid, on the addition of an alkali, it immediately precipitates a black powder. A solution of lead in caustic soda is precipitated in the metallic state as a grey mass. The reducing agent in all these cases is evidently the hydrogen in a nascent condition.

When silicon is thoroughly acted on by light, it is converted into a white body, to which the name Leukon has been given. The composition of this is also a matter of doubt, but it is a body of a somewhat similar composition to silicon, and in the presence of alkalis it behaves in the same way with some metallic salts. The mode of formation of leukon from silicon, under the influence of light, is also obscure; the most probable theory is that 4 atoms of water are decomposed, 4 of oxygen and 1 of hydrogen uniting to the silicon, and the other 3 of hydrogen being set free. According to this view, silicon is $\text{Si}_3 \text{H}_4 \text{O}_6$, and leukon is $\text{Si}_3 \text{H}_5 \text{O}_{10}$.

NEW LIGHT FOR ENLARGED PHOTOGRAPHS.

BY M. MC A. GAUDIN.

ENLARGING positives has made but very little progress since its *début*: this is the result of persisting in attempts to operate upon chloride of silver, which absolutely requires continuous clear solar light during several hours, while in operating with *iodide* of silver, and developing the picture with gallic acid, the process requires a light of one-fifth the power.

The obstacle principally alleged against the employment of iodide of silver is very puerile—that generally it does not give such fine tones as chloride of silver: but we do not see why the toning with salts of gold should not cause this inferiority to disappear, if sufficient attention be paid to this feature.

For my own part, I, who have studied for a very long time the process of development by means of gallic acid when I produce positives on collodion and upon paper with artificial light, I do not find that this charge of inferiority can be sustained, especially when operating by continuation upon *chloride* of silver.

It is a fact, which I believe to be general, that the insoluble compounds of silver sensitive to light become absolutely insensible whenever they are accompanied by their solvent. This has been shown in the case of iodide of silver when accompanied by iodide of potassium: not only is it then insensible to light, but, if it has already been exposed to light, a new luminous action in presence of iodide of potassium, will destroy the first impression, however intense it may have been. We can, therefore, imbue a cotton tissue, several yards in length, with iodide of silver insensible to light, prepared in full daylight with a slight addition of albumen, coagulated by passing a hot iron while the tissue is moist, then it may be washed in plenty of water, also in daylight, to free it almost entirely from the iodide of potassium, and then, to make use of it, it will be sufficient to sensitize it and expose it while moist to the action of the enlarging apparatus.

The same tissue, prepared with chloride of silver, and put to digest with a very weak solution of pure cyanide of potassium, should, for the same reason, be insensible to the action of light: and if this chloride of silver is somewhat slower to be impressed than iodide of silver, there is, on the other hand, the advantage of allowing the light to penetrate its entire thickness, on account of its transparency, as I have proved, and not give a merely superficial picture, like iodide of silver.

By proceeding in this manner, we should require for enlarging neither solar nor electric light, nor many hours' exposure, a small lime light and a few minutes' exposure will be sufficient.

The lime light is that which has served for some time for steamboat signal lights. It consists of a simple reservoir of oxygen gas, which is discharged under a pressure of 8 inches of water. This gas, by passing through a reservoir of ether, becomes saturated with it, and no longer explosive. It burns in the open air exactly like the flame of alcohol; but upon causing this portion of gas saturated with ether to arrive side by side with pure oxygen gas, but by means of a double cock, which regulates the portion of each to produce the maximum of brilliancy from the illuminating lime; the result is like a little sun, which, being fixed in the focus of a parabolic reflector, 8 inches in diameter, sends a bundle of parallel rays a distance of 10 yards, and which, collected by the enlarging apparatus, will, in one or two minutes, produce an impression on the continuous paper of chloride of silver, capable of assuming a fine bistre hue, by means of gallic acid and acetic, and the gold toning does the rest.

This apparatus always ready for use costs about £7, consisting of

Oxygen gasometer of 40 gallons	... £	2	0
Ether apparatus with lime jet	... £	3	10
Parabolic reflector	... £	0	15
Caoutchouc tubes	... £	0	15

£7 0

The light costs per minute for ether and oxygen gas about one penny halfpenny.—*La Lumière*

Upon this M. Saint Edme remarks, in *Cosmos*—"This experiment of M. Gaudin's is very interesting, as it is a means of producing the Drummond light with oxygen alone; but in a practical point of view, especially in photography, we do not perceive the advantage of substituting etherized oxygen for coal gas which is now so accessible. The luminous intensity and chemical nature of the rays remain the same, the etherized oxygen only supplying as combustible the carbonated hydrogens existing in coal gas. As to economy, it is evidently on the side of the Drummond light, as etherized oxygen in equal volume costs, at a minimum, from four to five francs the cubic *mètre*, and coal gas only a few centimes. The method proposed by M. Gaudin is applicable only to such cases as where coal gas is not attainable, or pure hydrogen cannot be prepared.

THE EMPLOYMENT OF PHOTOGENIC POWDERS FOR PRINTING VIGNETTES AND ENLARGED POSITIVES.

BY M. MO. A. GAUDIN.

The photogenic compounds of silver most employed in photography—the iodide, chloride, and bromide, when prepared by chemical precipitation, form a paste, which solidifies still more upon drying, and cannot be spread in a thin coating, by rubbing upon paper. It is quite otherwise with these same compounds when they are prepared by the action of the metalloids in vapour upon silver leaf. With time, this excessively divided silver completely loses its metallic lustre, and becomes transformed into transparent pellicles which can be spread upon paper with a tuft of cotton, in an homogeneous layer as thick or as thin as may be desired.

It is very easy to impregnate a sheet of paper of medium size, with iodide of silver, &c., by chemical precipitation, and that is the method generally pursued. But if we proceed to fix these photogenic compounds upon a limited portion of a sheet or upon a very large sheet of paper or tissue, the ordinary process loses its advantage.

Iodide of silver, for this new purpose, is prepared by placing a piece of silver leaf in a dish, the bottom of which is covered with iodine in scales covered with a piece of paper.

The silver fixed in position, the box is closed, and the reduction is allowed to go on until all trace of silver has disappeared, which takes place at the expiration of twenty-four hours, more or less, according to the temperature.

To produce chloride of silver by the same means, hypochlorite of lime in powder must be substituted for the iodine; in this case the reaction is much slower, and in order for it to take place, the piece of paper must be replaced by muslin gauze, and the dish must not be completely covered, because the action of the chloride takes place only by the intervention of the carbonic acid in the adjacent air.

As to the bromide, it is prepared by suspending a light muslin bag containing silver-leaf into a wide-mouthed bottle, into which some bromine is placed, and covered with water. In this case the operation proceeds as quickly as with iodine.

When we rub a coating of these powders upon paper by candle light, we cannot distinguish the coating by its colour, the whole appears white, and the only means of knowing where the coating exists is, by raising the paper to a level with the eye; wherever the coating exists, the surface appears dull or *mat*.

This was an impediment to the general employment of these powders, but upon reflecting that the employment of iodide of potassium presented a sure and ready means of rendering the iodide of silver specially insensible to light, a very ready method presented itself of forming coatings in broad daylight, when large surfaces are required to produce enlargements on. After covering a paper or a tissue as uniformly as possible, it suffices to stop all ulterior action of light, to immerse the sheet of paper or the tissue in a solution of iodide of potassium of 1 per cent., and dry them in the daylight, and sensitize them as wanted in the operating room, with a silver bath of 2 per cent. strength, and immediately expose them to the radiation of the enlarging apparatus.

For vignettes, the iodide of silver formed in the dark will be introduced into a wide-mouthed bottle, and after having added a minimum proportion of fused nitrate of silver, finely pulverised, rub the mixture upon the sheet of paper covered with a thin card, in which a rectangular elliptical, or circular square, has been cut, which will limit at will the place and the surface of the coating upon the sheet of paper.

It now only remains to cause a jet of steam to act upon it for a few seconds, to complete the preparation and render it proper to receive the luminous radiation behind a negative, and afterwards develop the picture, with gallic acid acidulated with acetic acid, as has been described many times before.

This process will be found very expeditious, in the space of twenty minutes, twenty sheets for vignettes may be prepared.—*La Lumière*.

PROPORTION OF SALT IN ALBUMENIZED PAPER.

BY ALFRED HARMAN.*

MR. CHAIRMAN AND GENTLEMEN,—I am induced to bring the results of these experiments before you for the purpose of arriving, if possible, at something like a conclusion as to the proportion of chloride to the albumen for albumenizing paper, which gives the best results for general purposes.

I know many professional albumenizers are ignorant of photography, and therefore cannot be aware of its requirements, and the statement which has been made that a certain albumenizer puts a handful of salt to a jugful of albumen proves some investigation into the subject to be necessary.

I have observed for some years past, that paper which I knew to be very slightly salted, always gave me more brilliant prints than most albumenized paper of commerce, which I believe contains about nine or ten grains of chloride to the

* Read at a meeting of the South London Society, on Thursday, Nov. 12th.

ounce of albumen. A print showed by Mr. Hart at a meeting of this Society, printed upon simply albumenized paper without any chloride whatever, confirmed this opinion, and I resolved to make these experiments to guide me and others in their printing operations.

I know that the strength of the silver bath would influence the quality of the print, according to the amount of chloride in the paper, therefore I used one of 60 grains per ounce of water, which I think is about the strength usually used by most photographers.

Here are four prints; No. 1, floated upon albumen with three grains of chloride of ammonia per ounce added; No. 2 with six grains; No. 3 with ten grains, and No. 4 with sixteen grains.

When a low salting formula is used, we can undoubtedly employ a much weaker silver bath, and still obtain equally brilliant prints as with a high salting formula and a strong bath, thus meeting the requirements of amateurs, who, when using strong silver solutions and not saving their washings, are at a very great loss through waste, &c.

I am sure a great deal of the difference of opinion regarding the strength of the silver bath for printing arises from different persons using paper prepared with various proportions of chloride in the albumen. One photographer, who is using paper with a small proportion of chloride, obtains good prints in a weak bath, and is surprised to find others with a similar bath cannot. The reason is obvious. The silver bath should in all cases be regulated according to the amount of chloride in the paper, and manufacturers should give the proportion of salt they use, to guide photographers as to the strength requisite for their bath.

As a matter of course, paper weakly salted prints slower than a highly salted sample, and likewise I have noticed the prints have a redder hue, but I invariably find that when such is the case, the toning takes place more evenly, and the finished prints are much finer. The chloride of ammonium gives a much redder colour in the frame than chloride of sodium, and for that reason I prefer it.

Remarks on this subject must necessarily be short, but I have no doubt will lead to much interesting discussion. I therefore place it in your hands, feeling confident that many valuable suggestions will be offered, and lead to improvements in that all-important branch of photography—*Printing*.

THE RECENTLY DISCOVERED EARLY PHOTOGRAPHS.

Our readers are familiar with the facts upon which the history of the alleged photographs of the eighteenth century is based. We now give the extracts from various letters and other documents from which these facts are obtained, and from which our readers can draw their own conclusions:—

EXTRACTS FROM LETTERS FROM MR. EDWARD PRICE, OF SOHO, NEAR BIRMINGHAM.

No. 1.

November 13th, 1862.

"With respect to the old sun pictures, I beg to assure you it will afford me great happiness to let you have them, and I will send them up with all the information I can collect, together with any other relics which I fancy would be interesting in your valuable museum."

No. 2.

November 26th, 1862.

"I beg leave to apprise you that I have this day sent from hence a small parcel containing a few old portraits of celebrated men, which I think will be interesting to you. My friend who borrowed the two sun pictures is from home, and I cannot get at them; but I enclose one on paper, and one on silver. The latter, I was assured by an old man who died eight years ago, was taken by Mr. Boulton, Mr. Watt, Dr. Small, and Mr. Franklin in front of the old house at Soho. This old man was Mr. Boulton's 'Cad.' He was his assistant and helpmate in all his experiments and journeys; he also knew all the members of the Lunar Society—Dr. Black, Mr. Roebuck, Dr. Small, James Watt, Mr. Edgeworth (father of the authoress), Dr. Johnson of Lichfield, and all the whole lot.* He has told me many a time about the great gentlemen coming every full-moon night, and stopping very late.

* Names of some of the members of the Lunar Society:—Samuel Galton of Birmingham, Matthew Boulton of Soho, James Watt of Soho, Captain Keir, Mr. Edgeworth, Dr. Withering, Dr. Stokes, Dr. Priestley, Dr. Farr, Dr. Davison,

"The room they used was like a Freemasons' lodge; indeed I believe the Lunar Society was really a lodge, because, when we pulled down the old library, I found traces of a lodge! For instance, the men pulled off the paper at the end of the room for lighting the fires, and upon the plaster I found traces of the emblems of masonry: there was (east) Δ and other signs; but, of course, you not being a mason, I cannot explain more.

"This old man Townsend Mr. Buckle at the Mint knew well. The old veteran died at the age of eighty-nine years, according to his widow's account, but ninety-two, of his own.

"He told me that Mr. Beechey, afterwards Sir William Beechey painted Matthew Boulton's picture"; and when he was at Soho, Mr. Boulton explained this invention of taking sun pictures.

"Sir William then went amongst all the artists, and got up a petition or memorial to Matthew Boulton and the Lunar Society, begging them to stop, because it (the secret), if made known, would be the means of 'shutting up the painters' shops.' This was poor old Townsend's expression.

"I recollect many years ago (say twenty), Mr. Boulton, the grandson of Matthew Boulton, asking me if I could write him an article about Soho for a dictionary, and I said I could not; he then sent me a letter to Mr. Watt about the matter, and I afterwards learnt that Mr. Watt had written the article for Lewis's 'Topographical Dictionary,' under the head of Handsworth in Staffordshire. I once saw this article in Mr. Watt's own hand writing, and it referred to these sun pictures. If you can get this work of Lewis's, I think you will find something about them.

"The framed picture is, I believe, copied from a painting by some celebrated lady painter; I forget her name, but I think it was Angelica Kauffman.

"Please, my dear sir, excuse this hasty scrawl, as I am very busy moving from this dear, dear old factory where I have been twenty-eight years.

"I have many tons of books and papers to sort over. * * *"

No. 3.

1st Dec., 1862.

"I am very much behind hand with my work, having to sort out this week about five tons of old books and papers previously to hiding adieu to this venerated spot. Please excuse my hasty writing. I should very much like to have a gossip with you, but for the present must forego that pleasure.

"Rest assured I will not lose sight of the other pictures, but will send them to you the moment I get bold of them again.

"I think the tinted one on paper is the reverse from a picture by Salvator Rosa. I believe I have seen a print of it somewhere; this, you will see, is all left-handed."

No. 4.

3 Dec., 1862.

"The clipping was done ten years ago, when I had no idea of what the picture was. I admired it, and asked my carpenter to put it in a frame for me. This is the one I mentioned as being framed; but I thought afterwards it would travel safer rolled up with the others, so I took it out of its frame and sent it to you clipped just as it was.

"I fancy the plain plate was laid against the sun picture of Soho House to preserve it, because you will perceive the picture is not secured. The least touch takes off the shadow; and if I had put any packing between them, I feel sure all would have been plain by the time you received it,—in fact, a blank.

"The other photos, you saw had a number scored on the face, 7, 6, or 9; and these I still hope to get for you in a day or two.

"I don't want to tease you too much, but suppose I could give you a clue to the camera which made these pictures? I had it once! and did not know what it was for. Some thirteen years ago, I showed it to a friend of mine, and he appeared so delighted with it that I could not help giving it to him.

"When I cleared out Mr. Boulton's old library, Miss Wilkinson (aunt to the present Mr. Bolton) told me to take away 'all that rubbish,' and do what I liked with it. The Camera and these old pictures were amongst the rubbish. Little did I think what they were.

"Well, some five or six years after I had parted with the camera, my friend told me it was a most excellent instrument, and that he had taken some capital pictures with it. I then wished for it again, but it was too late. That friend was schoolmaster at Trentham, in Staffordshire, to a school supported by the good Duchess of Sutherland. Her Grace was very fond of this Mr. Powell, and used to pet him and his large family, giving him every encouragement for displaying a very ingenious mind. This Mr. Powell left her Grace's employ about six years ago, or perhaps less, and became tutor to Dr. Marks's little men."

No. 5.

13th December, 1862.

"I know you have got into deep responsibility over these sun pictures, and be assured I shall do my utmost to assist you in meeting all doubts.

"I could not possibly send you a long letter to-day.

"I merely enclose a proof-sheet from Lewis, which merely refers to pictures in oil."

Mr. Day, Sir W. Herschel, Sir Joseph Banks, Dr. Solander, Dr. Arelius, Dr. Small, Benjamin Franklin, Dr. Black, Mr. Roebuck, Dr. Johnson of Lichfield, Mr. Wedgewood.

"20, Upper Southwick Street,

Cambridge Square,

30th Oct., 1863.

"DEAR SIR,—Beechey's portrait of Matthew Boulton was exhibited at the Royal Academy in 1799, and is thus described:—

"209. Portrait of Mr. Boulton, of Soho, Staffordshire: Sir W. Beechey, R.A."

"I have found a very curious Catalogue of an Exhibition of Polygraphic Pictures, which I have sent to Dr. Diamond. The title states that they are 'copied by Chymical and Mechanical Process, the invention of Mr. Joseph Booth.' There is no date; and I have requested Dr. Diamond to show it to you. Believe me to remain,

"Very truly yours,
F. Smith, Esq."

† "The manufacture of astronomical clocks for some years was carried on at Soho; and the art of copying pictures in oil colours, called polygraphie, was also invented and pursued here under the direction of Mr. Francis

"We must find out Eginton. There are many specimens of his glass-painting in England—oué, a most splendid piece of work, at our St. Paul's Church, Birmingham; but he has been dead many years. I believe I have two pictures painted in oil by this process.
 "No one is now alive who can recollect Soho House before it was altered; at least I think not, but will inquire.
 "Excuse haste—I will write again.
 "I have found out Mr. John Powell's mother; that's something."

No. 6.

"16th December, 1862.

"There will be no necessity for advertising Mr. John Powell, as I shall have his address to-morrow from his sister, and will then write him.
 "I am quite interested in your pursuit, and begin to feel annoyed and sorry that I had not the pleasure of your acquaintance years ago. What a rich mine of relics I might have saved, which, through ignorance, are now gone out of reach!
 "I saw an auctioneer to-day, who, some years ago, was a common dealer and broker. He knew Mr. Powell; and when I inquired if he knew his address, the subject of the sun pictures came up. He reminded me that, some years ago, when I turned out all the rubbish and waste paper from the library at Soho House, he bought the old scrap paper, and amongst it, was a very curious picture which he could not make out. I did not recollect any picture being amongst the rubbish. He says that, in sorting it over, he found it, and put it on one side; since then, he has frequently brought it out, and has always become bewildered as to what it is. He says it is neither chalk, crayon, Indian ink, paint, or painting. He will bring it up for me to see; it is in two parts, he says, and from his general description, I suppose it is a brother or sister of those I sent you.
 "I have not yet found any one who could recognize Old Soho House. Samuel Vale, whom Mr. Buckle knows well, says he recollects it being altered once, but cannot tell what it was like before the alteration.
 "The publications of the Lunar Society are in the 'Philosophical Transactions.' These 'Lunatics,' as they are called, threw out such outlandish ideas, that, instead of Lunar, they were called 'Lunatics.' But, of course, the records or memos. of their private proceedings may never come to light. They put forth to the world only just what they thought proper. Their private papers, I believe, will never come to light. They were truly great men.
 "Buckle has heard from Mr. Watt (the late Mr. Watt, I mean) more about them than I can tell you.
 "Benjamin Franklin was among them at one time. Dr. Priestly was a firm member. Dr. Black came all the way from Scotland to attend these meetings on full-moon nights (as poor veteran Townsend used to call their meeting); Dr. Small, from Birmingham; Mr. Edgeworth, from Lichfield (father of Maria Edgeworth); Mr. Wedgwood (the greatest potter); Dr. Johnson; Dr. Darwin (the great botanist). I cannot think of the others; they are all gone. Mr. Galton, the Quaker, too. J. P. Muirhead, Esq., the friend and relative of the late James Watt, published lately (three or four years ago) a new edition of the 'Life of Watt.' All in this book is authentic; because I know Mr. Watt left him all his papers, books, drawings, and memoranda, &c., for the purpose of writing this life. Although I have never seen the book, I believe it refers to these sun pictures, as well as to the transactions of the Lunar Society.
 "The article for Handsworth in Lewis was, of course, written by the late J. Watt.
 "I will write again when I hear from Mr. Powell, and will not 'budge' till we have succeeded.

No. 7.

"19th December, 1862.

"I have obtained Mr. Powell's address, and have written him.
 "The broker, who has got the other pictures, expects to be paid. Of course I made very light of them, as he bought them merely as waste paper. I said he ought to return them to me as such. I asked him what he wanted for them, and he merely said he would consider of it. They should be secured by all means: they are very beautiful.
 "I shall hear from Mr. Powell in a post or two. Singular enough, he was in Birmingham on Monday, and I did not know it. His address is 22, Liverpool Road, Manchester."

Copy of Telegram from Mr. F. P. Smith to Mr. Price.

"Don't give him time to think, but get pictures at once, lowest price you can. F. P. S."

No. 8.

"22nd December, 1862.

"Do not think by my absence that I am deserting you.
 "On Saturday morning I had to meet Mr. Boulton at Malvern, and only came home late to-night, very tired. I found your telegram, and will see Mr. Shread, the auctioneer, to-morrow, and, if possible, will get the picture.
 "Mr. Powell's letter* is enclosed. He will, I know, do all he can to find the old relic camera.
 "In thinking over these pictures, I recollect old Townsend, in his gossip, telling me that they (the great men) used to have pictures on the table (not the pictures themselves, but the likeness of the pictures), and the way he tried to show me was nothing more or less than the camera obscura. He explained, 'they' were in a dark tent, and nothing but a picture on the table. By some process they secured this shadow: I have no doubt whatever about it.

Eginton, to whom it was subsequently resigned, and who became celebrated for his paintings on glass."—Lewis's Topographical Dictionary, art. HANDSWORTH.

Copy of Mr. Powell's Letter. (No. 9).

"21st December, 1862.

"Mr. Gell handed me your letter, and that of the 18th inst. is to hand.
 "It has long been a source of regret to me that, on my leaving my house at Trentham, the old and much-valued relic, the camera, vanished—whether sold by auction, or carried away by some friend while I was absent in Ireland. I have never been able to make out; however, as you are interested in its recovery, nothing would give me greater pleasure than to restore it to you. I shall, therefore, renew my inquiries, and if I can get any clue to it will not fail to let you know."

"I have written to Mr. Powell to tell him how interested I should be to get hold of my old camera again. He will do his best."

No. 10.

"23rd December, 1862.

"I have much pleasure in apprising you that I have this evening dispatched to your address two parcels; containing the pictures which I got from Mr. Shread, the auctioneer. He set a great value upon them, and I was at one time afraid he would not loose them. 'Will £10 do?' said he. '£10!' said I; 'you mean 10s.' After a good deal of bantering, I succeeded in getting them for £4 4s., and I think, under the circumstances, I did very well. They are really very beautiful. The large one in two parts is most beautiful; but where is the original painting? Some of your great men may recognize it."

No. 11.

"26th December, 1862.

"Yours to hand, with enclosure and receipt herewith for the four guineas.
 "Little did I think, when I had the pleasure of seeing you here, and showing you these old curiosities, that it would have turned out so interesting.
 "I fancy I have bothered somebody by turning up these mysterious relics. I think I have nearly exhausted my store of information on the subject; yet one thing I recollect. This old camera was about 12 inches cube, made of oak, roughly; and, and to the best of my recollection, the lens was not more than 2½ or 3 inches diameter, but there were some moveable parts in it. All this Mr. Powell will explain.
 "The whole of the rooms at Soho have long since been cleaned out, and the house left to the incumbent of the church. There is, therefore, nothing whatever (not even a scrap of paper) left there belonging to Matthew Boulton. What remains of the correspondence and books I have in my own keeping, and these must soon be dispersed for want of room. The old factory is coming down, and there are many reasons why a regular turn-out should now be made. But before I begin to destroy any papers, you shall be welcome to look at them. Bear in mind, they weigh about three tons.
 "The writing at the back of 'Flora,' was done by the broker, directly after his clearance from Soho; it was at that time a mere guess from what I had let out." * * * * *

"Depend upon it, these sun pictures were produced by a process with the help of the camera obscura. It would not, I suppose, have been possible to have got such large paper as the picture in two parts."

[Copy of a Letter from Messrs. J. Hollingsworth and Company, paper-makers, Turkey Mills, Maidstone;—

No. 12.

"29th Dec. 1862.

"In reply to your letter of the 26th, with respect to the exceedingly rough foolscap paper made by Whatman, the only information we can give you upon the subject is, that Mr. Whatman had the Mills about 100 years ago, and think that the name of Whatman was first put on the paper only, and after a few years the date of the year; and when we purchased the Mills, in 1794, the date was then in, and have continued the date of the year ever since.

"We remain, Sir, yours very faithfully,
 (Signed) "HOLLINGSWORTH and Co.

"F. P. Smith, Esq.]"

No. 13.

"30th Dec. 1862.

"The first thing is to retain Mr. Powell, to hunt up the camera, and get his account of it."
 "I shall get Powell's answer in a post or two."

[Extract from Mr. Powell's letter:—

No. 14.

"31st Dec., 1862.

"I have written to a friend at Trentham, who will, I know, make diligent search for the camera. I have such a vivid recollection of the old favourite, that if I can get it back again in a hundred pieces, I can restore it to its original condition."

No. 15.

"3rd Jan., 1863.

"In the record of the International Exhibition, part 12, page 565, reference is made to experiments made by Davy and Wedgwood* for copying paintings on glass, in 1802. The author of this article seems to have a glimmer of this great mystery."

No. 16.

"19th Jan., 1863.

"The auctioneer, Mr. Shread, has found two more beautiful old sun pictures, copies of paintings, amongst the rubbish I sold him. Had I better secure them?"

No. 17.

"5th Feb., 1863.

"Boulton and Fothergill sold pictures painted in oil by the dozens, at very low prices; and I firmly believe I have a clue to the secret, but am not yet quite ready to give you details. When I am, I will do myself the pleasure of riding up to South Kensington."

* "Wedgwood was very intimate with Boulton and Watt; and I have copies of letters to him from Boulton, but nothing about this subject."

Finish from the dead colour and retouching Tragedy and Comedy Heads, and Melpomony, 15s.; and Thalia, 16s. Figures, 4 in all, 7/6

£13 7 6

"SIR,—In the above I have conform'd to the Order as near as the very low prices to which I was limited would permit some alterations I have been obliged to make on that act, particularly in the four Historical square ones which should have been according to order from 15s. to 20s. instead of which you will find one pair from West at 25s. each and one pair from Angelica at 21s. each which were the lowest Historical Pictures I could send the 16 Oval or Medallion formed Pictures are of different sizes; and altho' some of them are something higher priced than what was fixed, others are lower, so that upon the average they will be nearly the price at which they were ordered.

"I hope they will meet yr approbation and am, Sir, Your Obedt Servt, Fr. EGINTON."

them very extensively. I have many letters from purchasers, and from the entries in the books there must still be a great many of these pictures amongst the nobility and gentry in London, for they bought largely, and at such very low prices. I think Government had something to do with the suspension of this trade, because the person who held the secret was offered a pension, but Matthew Boulton objected to it in a letter to Lord Dartmouth, who was, I believe, Lord Chamberlain."

No. 23.

"28th May, 1863.

"I am in doubts whether we can prove much or anything from my old papers to establish the silver plates. But the picture-copying there is no doubt about.

"Eginton's name is erased in many places in the old books; all this is a mystery.

"Since I began this note, I have received your message. What can I do but send you my bundle of old papers? I cannot find anything about the silver plates. Boulton and Eginton, I believe, alone knew the secret, and with them it died. Eginton, I believe, came to Boulton; and they perfected some copies of pictures. A painter named Barney, and another named Wilson, had these copies to paint in oil after Eginton had transferred them from the originals. If you read the letters and papers through, I think you will be of the same opinion; and these pictures were sold by way of trade to Boulton and Pothergill's customers, the same as they were sold teapots or buttons.

"London, 10 July 1781.

"GENT,—We send you orders for some few Pictures, which must be painted in a much more masterly manner than the Pictures you sent as samples. They are all to be painted on canvas, the particulars on the other side—you will please to write us by return of post says the time they certainly can be got ready—& we likewise wish to know if the same subjects cannot be done on diff. sizes and shapes—suppose—Rinaldo preventing Armyna from stabbing herself—you give us the size of 50 lu high by 40 Inches wide Can this same picture be done 24 In high by 30 inches wide—we shall likewise want the Vale of Tivoli, some Views of Naples & a variety of Views of Italy & likewise of other diff. Views—the sizes which best please 24 In by 30 In—you'll not delay giving us the Particulars—we cannot help thinking your prices very high—and request you'll further consider and give us another list of prices—we mean the Pictures only without the frames as those we choose to have made ourselves—the wise men's offering must be of size abt 24 by 30.

"For Self & Co

"Yr. H. Ser.

"RICHD. CLARKE."

The Pictures marked x we have got here.

F. P. S.

* Copy of a Letter to the Right Honourable the Earl of Dartmouth.

"MY LORD,—A few days ago I received a letter from Sir John Dalrymple, dated Dublin, May 27, in which he surprises me by saying, 'I have written to Sir Gray Cooper to have a pension of £20 per annum for Mr. Eginton; so if there is any stop, write me of it to Scotland, and I will get it set to rights, as I know nothing but inattention can stop it.'

"As I think I cannot with propriety write to Sir Gray Cooper upon that matter, having not the honour of being known to him, and as I have never mentioned the subject to him, or any person besides your Lordship, I hope, therefore, to be pardoned for thus troubling you with my sentiments and wishes.

"In the first place, I wish to have an entire stop put to the pension, because Mr. Eginton hath no claim nor expectations. I pay him by the year, and consequently he is already paid by me for all the three or four months spent in that business; and as to an overplus reward for his secrecy, I know how to do that more effectually and with more prudence than giving him annually £20, which will only serve to keep up the remembrance of that business, and therefore it is impolitical.

"Besides, it might perhaps be injurious to me, as such a pension would tend to make him more independent of me and my manufacture.

"His attachment to me, his knowing that no use hath been made of the things, the obligation he is under to me, and his own natural caution and prudence renders me firmly persuaded that the scheme will die away in his memory, or at least will never be mentioned.

"If anybody is entitled to any pecuniary reward in this business it is myself, because I have not only bestowed some time upon it, but have actually expended in money between one and two hundred pounds, as I can readily convince your Lordship when I have the honour of seeing you at Soho; and although I was induced by to believe that I was working at the request and under the authority of a noble lord (whose wisdom and virtue I revere), yet I never intended making any charge to Government of my expenses or for my trouble.

"All that I have now to request or your Lordship is that a negative be put upon the pension.

"My lord, your lordship's most dutiful, most obliged, and most faithful, humble servant,

"M. B."

Angelica "Kauffman", De Louthembourg, and others supplied the originals; but they little thought what use was going to be made of them.
 "Mr. B. says, needs no answer."
 "I now send you the other transfers on paper which I bought of Mr. Shread, the auctioneer.
 "If you require to see some of these oil copies, I know where there are two; but I should think there are many in London."

No. 25.

"9th July 1863.

"You startle me very much about the lady who is writing the Life of Josiah Wedgwood.

"In all the correspondence I have, there is no mention whatever of Wedgwood in connection with the picture manufacture, or with Matthew Boulton or Eginton on picture business, except when W. buys a picture. If she has the invoice of this camera made out in Josiah Wedgwood's name, thus:—

177	Mr. Josiah Wedgwood	
June 9	Bought of John	
One Camera with Slide, Lense, &c. complete in Oak frame	£—

"Soho, 8 Jan., '82.

"Mr. Barney, Cr.
 } Finishing a Time and Cupid £3 3 0
 } " Cupid struggle to recover his arrows 73 | 6 3 13 6
 } Hebe—finishing or retouches 0 10 6
 * Mr. Boulton's Stratonic 15 15 0
 } Wise Men's Offering 2 2 0
 } Graces Dancing 1 1 0
 } Trennor & Juibica 5 5 0
 } Null 2 Circles, Cupid Triumphant & Cupid hound to a Tree Charg'd before.
 } Return of Telemachus 7 7 0
 } Trennor 3 3 0
 } Time and Cupid 3 3 0
 "Edtd. in his Book at Soho, under the date the 31st Xr. 1781.—J. H."

I should indeed be astonished; but I believe that the camera I so unfortunately gave to Mr. John Powell was unique—the very first ever made, and made at Soho under the direction of Matthew Boulton and the members of the Lunar Society.

"This lady must be careful in not confounding the original Wedgwood

* "Mrs. Angelica Kauffman presents her compliments to Mr. Boulton, acquaints him that, according to his desire, she has done the little Picture which is to be a companion to the Penelope. It represents 'Calyppo mournful after the departure of Ulysses.'

"Mrs. Angelica flatters herself that Mr. Boulton will approve of it, as she has finished it with all possible care.

"London, " June the 12, 1778."

"Golden Square." "Mr. B. say'd he had seen her since she wrote the above."

"Sir,—I had the plaisir to receive your two letters and would have had the satisfaction to answer them immediately had j not been in the country, j also receive your draught of 15.£ 15s. and shall have the plaisir of letting you know when j have received the payment of it. Mr. Picot in my absence has delivered your Picture to Mr. Matheus else j should with plaisir have send it to you according your direction. j shall remain till the later end of 7bris at Shooters hill, and if as j hope you are pleased with your little picture and will, according to what you was pleased to tell me, want some more, j should take it as a favour if you will let me know soon and direct your letters to me at Shooters hill opposite the Bull, Kent, and j will make all speed j can to lett you have the remaining picture soonest possible. j am with regard

"Sir
 "Your most obditeent Servant
 "DE LOUTHERBOURG.

"Shooters hill, 17 August 1777."
 "— Boulton & Fothergill, Esqrs.
 "Soho, near Birmingham."

"W'hampton Sep. 22d, 1781.

"Mr. Hodges,
 "Sir,—After considering the great risk you will run in sending the picture by the Coach, with the uncertainty even of its being dry against the time fixed, I conclude it of much less consequence that I should bestow a few days more in rendering the Picture I am now at work on equal to the Original, than to have one totally spoiled in the carriage and the intention of the whole order frustrated thereby. I have therefore sent you the Original as a companion to the other, and you may depend on having the remaining picture returned to you equal to either of the former, and I shall have the satisfaction of completing my part of the order in due time. If these pictures are not sent away till monday, there should be some white of egg given to the Time & Cupid, has it is scarcely dry enough to bear the Carriage.

"Please, if you can, to return by the bearer the Time & Cupid which is to be painted for Mr. Boulton, with the Circle of the Graces breaking Cupid's bow for Mr. Wedgwood.

"I am, Sir, your obt St.
 "JOSH. BARNEY."

"Mr. Jon. Hodges, Soho."

"This was a bad damaged finish'd piece—but repainted and mended for Mr. Boulton.

"This from an impression for Mr. Wedgwood.
 "This on copper finished by somebody, but retouched by Mr. Barney for Mr. Boulton.

"This remains unaccounted for—to be settled by him and Mr. Boulton.
 "These retouch'd in places only.

"This finished very highly from an impression being intended in lieu of an Original one sent Clarke & Green thro' shortness of Time.

"This finish'd from the plain for ordr. Capt. D. A.—F.
 "This finish'd from an impression.

"This do. do. do."

with his sons. One of his sons, we well know, tried photography with Davy.*

"I am beginning to feel jealous about it, and shall anxiously be looking out for the work; it is sure to be interesting.

"I shall endeavour to go over to Trentham to-morrow, without Mr. Powell, and feel about for the desired curiosity.

"Trentham is close to the Potteries, where Wedgwood's home and works are; but I feel convinced they have got the wrong parties. They have got hold of Davy and Wedgwood, not Boulton and Wedgwood. You may depend upon it this secret was allowed to die out with the deaths of Eginton and the Lunatics, and all traces of it were destroyed at the instigation of the Royal Academy and some members of the Government.

"In my old letter-books hundreds of pages have been torn out, besides many erasures.

"Wedgwood, the great potter, belonged to the Lunar Society, and would, consequently, know about the sun pictures; he had four sons, all of them clever. The father would naturally instruct his children in the discoveries of Boulton and the Lunatics: hence Wedgwood and Humphrey Davy trying their hands at it."

No. 27.

"7th Aug., 1863.

"I regret to tell you, I cannot find out anything about the camera. At Trentham there is no one that can recollect it. The man who prepared the inventory of Powell's effects assures me it was not included, and he never saw it. I am fearful it is gone, although Powell says he hopes to trace it.

"The pictures Mr. Hamilton refers to are two curious paintings by Louthembourg; they were sold by auction at our Auction-rooms at Birmingham, and were described as the products of the process of Boulton and Watt. This was directly after those articles appeared in the Birmingham papers."

Extract from Mr. Edward Price's letter, dated November 1st, 1863.

"I do not believe that Davy and Thomas Wedgwood were really the discoverers of photography. I still maintain that the art of taking sun pictures emanated from the Lunar Society, of which Josiah Wedgwood was a member, and by whom the secret, in all probability, was divulged to his son Thomas, who afterwards imparted it, as far as he could, to that clever philosopher Humphrey Davy, and the two set to work to make something out of it, and to a certain extent succeeded.

"I am truly sorry to tell you that Mr. Powell has not yet written to me in reply to my last three notes, and he has not yet sent the photograph which he took from the old camera.

"I believe he is now in the Potteries, about Trentham, Burslem, &c., hunting after the missing relic, and I trust it will turn up after all. I shall write him by this night's post, to tell him to write to you direct in time for Tuesday.

"As to a picture coloured in oil by Eginton, I beg to say that I will send you one copied from the celebrated picture of Murillo's 'The Good Shepherd,' or the 'Infant Jesus.' I think the original is at the National Gallery. You will observe that it is reversed; for instance, the crook is in the hand on the opposite side to where it is in the original. This picture has been engraved over and over again; and a very good impression is in 'Family Devotions' (published some years ago by Tallis), vol. ii. p. 124.

"This copy of Eginton's was given to me by the sister-in-law of Mr. Matthew Robinson Boulton, and I will let you have it, to enable you to see how they finished their work.

"I have also two other oil paintings, copies of Eginton's 'Cupid being bound by the Graces,' and the other 'Cupid being drawn in a Chariot by the Graces.' They are both finished in oil; but they are reverses.

"If you want these, you must please telegraph soon in the morning, as they are not at home, but at my mother's.

"Yours sincerely,
 "EDWARD PRICE."

* "Extract from Miss Metyard's letter, 2nd Nov. 1863.

"DEAR SIR,—You may with safety refer the first experiments in photography to as early a date as 1790 or 1791. In the latter year I find Thomas Wedgwood (third surviving son of Josiah Wedgwood), sending his camera to Birmingham to be mended; ordering silver cylinders, solid in form, highly polished, and turned on a lathe; and desiring to have sent him a coil of silver wire of extraordinary fineness. He has also common barometer tubes blown with a bulb.

"The first process seems to have consisted in laying the nitrate of silver upon paper, and then, by means of the camera obscura and the solar rays acting on the paper, a perfect impression was obtained of any object in half a second; but the image soon faded on exposure to light, and after a while disappeared. Subsequent improvements were made, but the result was not satisfactory, even at a later date, when Sir H. Davy assisted in these experiments. Hence, all early photographs have a faded appearance—a defect probably due to the quality of the chemical agents employed, rather than to a want of manipulative dexterity. This and other chemical experiments were extraordinary, considered relatively to a youth of 18 or 19 years of age, and the then somewhat early stage of philosophical knowledge and analytical training. But even before this, there can be no doubt that young Wedgwood, and his father's resident chemist, Alexander Chisholm (who entered the elder Wedgwood's service in 1781), had worked together in pleasant companionship, and we may very reasonably assume that the two photographs in your possession were the results of this companionship in science. One of the photographs is undoubtedly a representative picture of the breakfast-table at Etruria Hall, as we see upon it articles of jasperware, adorned with cameo-work of the usual kind.

"Thomas Wedgwood, who died, I think, in 1805, was a wonderful man. His philosophical and metaphysical theories were as profound as they were far in advance of his time; and it is said that, in relation to light and heat, he anticipated some of the discoveries of our own age.

"This is all I can tell you. I am neither a philosopher nor a chemist; so please pardon whatever may be incorrect in this statement, though, as far as facts are concerned, it is pretty accurate. I write, too, in a hurry to save time.

"In January, upon my return from Liverpool, I may be better able to add to your knowledge.

"Please consider this as private, except to your Society; for my crude statement is worth nothing, except for the truth of its few facts.

"I am, dear Sir,
 &c. &c."

Extract from Mr. Edward Price's letter, dated November 2nd, 1863.

"These pictures are invaluable to me; they are my only and really last connexion with Miss Wilkinson; and therefore, do take care of them, and return them all safe.

"This Miss Wilkinson is a most extraordinary lady. She was the bosom friend of James Watt, and the sister-in-law of Matthew Boulton. She is still alive, but quite childish.

"These pictures were given to me in Matthew Boulton's library at Soho. Miss Wilkinson said, 'Here, Edward, here are the relics of the Soho; take them, and preserve them as long as you live. The Boultons may not have the honour which may be due to them; but, never mind, the Watt will.'

"I can only repeat that these pictures were given to me by Miss Wilkinson, and she said (many years afterwards) they were the most precious gems in her line; that I must keep them, and show them as long as I lived: they were a mystery.

"My mother has had the two circular pictures at home about 20 years, and I have had the other about 17 years. Neither of them were out of Soho House up to that time for the last 50 years, as I have proofs.

"Yours sincerely,
"EDWARD PRICE"

"I have heard nothing of Mr. Powell and the old photo and camera; but I hope you have."

Other documents bearing on the subject:—

"Mr. Barney. Soho, 25th August, 1781.
"Sir,—I am sorry I was absent when you call'd yesterday. This morning I deliver'd to your man the painting of Telemachus with two blanks for painting the same upon. Messrs. B. & F. have undertaken these pieces at about £7 net. Mem. *not* including their general expences attending the sale, &c.; therefore, as Mr. Boulton desires they may be well executed, he will not stipulate you in the charge thereof, but as you are acquainted what he will get for them, he leaves it to you to render them as moderate as you can, but begs they may be good pieces and exactly alike, for they go as mechanical paintings. I could wish to receive your reply to the above; also to intimate how soon you guess they can be done. Besides these two of Telemachus there are wanted two of Time and Cupid—2 of Jubica and Trenmore (one of which only wants repairing), the other three to be deliver'd in the dead color'd state. The time limited for the whole is to be in London by the end of Sept. Please to signify what of 'em (if not all) you can undertake.

"In expectation of hearing from you soon,

"I remain very respectfully,

"Sir,

"Your obedt. hble. Servt.,
"Jno. HODGES."

"Mr. Hodges.

"Sir,—Mr. Barney was hear last night, and inform'd me he was going to London, and that Mr. B. wish'd him to take the picture of Stratoney to finish from the original of Mr. West, and that Mr. B. was pleas'd to say I might have the picture again when finish'd to correct the coloring of one for my self at my leisure, for which I shall be much oblig'd to him—

"The print of that subject which you Brought is ready for Transferring, and if you have any canvas of that size, it shall be don immediatly and Mr. B. may have his chois.

"I am, Sir,

"Yr. obdt. hble. Servt.,
"FR. EGINTON."

"July 5, 1781."

"Mr. Hodges.

"January 18, 1782.

"Sir,—The plates which I have an immediat ocation for are Time and Cupid, and also Telemachus—and if Mr. B. will pleas to favour me with the respective pictures to finish one of each from, you may depend upon the greatest care being taken of them, and safely return'd by

"Yr. oblig'd hble. Servt.,
"FR. EGINTON."

"Mr. F. Eginton.

"Soho, 17th Xbr, '81.

"Sir,—Inclosed are two impressions, Penelope and Calypso, which you are requested to transfer on the two Copper plates herewith. These are wanted for the same order as the Time and Cupid, Jubica, &c.; therefore I must get 'em done, say finish'd in a mastery stile. The sooner they are done, the more you will oblige Messrs. B. and F.

"I am, Sir,

"Your very obedt. Servt.,
"Jno. HODGES"

P.S. Should an impression of Trenmore be ready, please to send it per bearer, as the others already received wait its arrival.

"Mr. Barney.

"Soho, 15 August, '81.

"Sir,—Your favour I have received, and in reply have to inform you that the following paintings will be wanted for certain by the end of Sept.—viz. Two Telemachus on his return, Two Time and Cupid.

"The last will be deliver'd to you in the dead color'd state; the first to be done from the plain. If you think you can execute these (and perhaps two more pieces) by the time, provided you set off as you mention, please to give a line. I shall prepare the straining-frames, canvass, &c., ready to begin the Telemachus's, and hope for your answer about send; them to W^hamp-ton to be ready against your arrival.

"I am, for Messrs. Boulton & Fothergill,

"Sir,
"Your obedt. hble. Servt.,

"7, Quality Court, Chancery Lane, W.C.

"October 30th, 1863.

"DEAR SIR,—I examined the piece of plate you gave me when last at the Museum, and found plenty of silver upon the coating. I was waiting until you sent me the piece of picture to assay. I am, however, quite satisfied that no silver was in the piece you gave me before.

"I remain,

"Yours very truly,
"DUGALD CAMPBELL."

"F. P. Smith, Esq."

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting was held in the City of London College, Leadenhall Street, on the evening of Thursday, Nov. 12th. The Rev. F. F. Statham, M.A., F.G.S., in the chair.

The minutes of a previous meeting were read and confirmed.

Mr. WHARTON SIMPSON called attention to some fine specimens of Mr. Dallas' photo-electric engraving, and to some charming specimens of art-photography by Mr. Wingfield.

The SECRETARY called attention to a beautiful specimen of card portraiture by Mr. Rejlander, to a portrait by Mr. Miers, and to a transferred albumen film by Mr. Harmer. It had been attached to the concave surface of a watch, coloured in water colours, and then backed up with white; presenting, when the convex side was examined, a very pleasing effect. The Secretary remarked that the specimen was tinted in water colours, but he thought oil would have given a richer effect.

Mr. JABEZ HUGHES exhibited two very fine 10 by 8 portraits taken with Dallmeyer's No. 2 triple lens, open aperture; the exposure in a glass room, with moderate light, was about 30 or 40 seconds. They were especially admired for their roundness and the admirable definition in every part they presented.

The SECRETARY then read a paper on Photography in India, by Mr. Warner (see p. 548), and exhibited some models of the application suggested for preserving moisture.

The CHAIRMAN remarked that possibly they might be found of service in this country during hot weather.

Mr. WALL said he thought that Mr. Warner had scarcely done full justice to Indian photographs. There were in the International Exhibition some vignette heads so fine that he thought he gave them the highest praise when he said they were nearly equal to those of Mr. T. R. Williams.

Mr. ALFRED HARMAN then read a short paper on the proportion of chlorides in albumenized paper (see p. 556). He also exhibited some specimens illustrating the position he assumed. There were four prints from the same negative, a very thin one; the first was on paper prepared with 3 grains to the ounce, and the others with 6, 10, and 15 grains respectively. They were all excited on a 60-grain nitrate bath, and printed, toned, and fixed together. Those with the least salt unquestionably possessed the greatest vigour, but the contrast was not so marked, Mr. Harman observed by artificial light as by daylight.

Mr. WALL asked if it would not be best to proportion the amount of chloride to the quality of the negative.

Mr. HARMAN said that this might be done to some extent, but could not conveniently be carried out thoroughly, as it would be impossible to have a differently prepared negative for every variety of negative. A difficulty arose, moreover, from the unwillingness of manufacturers to state the formula by which their papers respectively were prepared.

The CHAIRMAN asked if it would not be easy for photographers to test these papers, and thus ascertain the proportion of chloride present.

Mr. MARTIN said this might be done by soaking a known quantity of paper in cold water to remove all the albumen. This could then be coagulated by nitric acid, and the amount of chloride present ascertained by precipitating it with a standard solution of nitrate of silver.

Mr. PRICE said that some of the chlorides, barium for instance, formed a compound with albumen, and could not be separated and estimated in this way. He had found he could not get a barium paper because manufacturers said the compound it formed with the albumen caused some difficulties.

Mr. SEBASTIAN DAVIS thought there would be insuperable difficulties in forming a correct estimate. The proportion of albumen on different sheets of paper varied according to the absorbent qualities of the paper, and the temperature of the rooms in which the albumenizing was conducted. The organic salts present would also mar the estimate.

Mr. SIMPSON said it would be clearly impossible from the causes named, and others, for photographers to arrive at a definite estimate of the proportion of salt used, and if it were possible they would not undertake such a troublesome operation. There was, however, a much simpler plan quite within their power. So soon as it was determined to be of vital importance to them to know the proportion of salt used, they had nothing to do but decline to use the paper of any manufacturer who

refused to give them the necessary information. If they declined to use any paper in regard to which a secret was maintained, all difficulty of that kind would soon disappear.

Mr. MARTIN confirmed Mr. Davis's remarks by stating that even the use of a deep or a shallow vessel for holding the albumen solution would cause a variation in the proportion of salt the paper received.

Mr. HART said he thought that any albumenizer would be willing to state the number of grains of active chloride present in his paper if it were demanded, even if he made a secret of the base or bases used. He would be happy to prepare paper with chloride of barium if any one ordered it.

The CHAIRMAN suggested that if the paper bore a mark indicating the strength of salt used it would be an advantage.

Mr. JABEZ HUGHES said he believed that albumenizers had really very little to conceal. The common practice was to use about 10 grains of chloride of sodium or of ammonium to each ounce of solution; the proportion varied from about 8 grains to 12 grains. But suppose they knew all about it, how much wiser were they? The question was still open as to the strength of silver bath required with a given proportion of chloride in the paper. And even if that were determined they were still in a state of uncertainty, for the last sheets, which were albumenized upon any given quantity of solution, would have a larger proportion of salt than the others from the evaporation of a certain amount of water. Again, some sheets were more absorbent than others, and the proportion of salt would be disturbed by that cause. On the whole, he thought that more harm than good would be done by manufacturers stating the proportion of salt the paper was supposed to contain, for it must often be a misleading statement. The point now to be established was as to the advantage of a small proportion of salt. In Mr. Harman's specimens he could not see much difference; there appeared to him to be no greater difference than might be produced by accidental causes in the same paper. Such, at least, appeared to him to be the case in examining them by artificial light, and they did not prove anything certainly as to influence of the salting. There was another question he thought more important and more open to them; he referred to the strength of the silver bath. The strength of this was in their own hands, as they all made their own. A short time ago an impression prevailed as to the importance of strong baths, and 80 grains and 100 grains to the ounce of water were commonly used. He had recently talked with a gentleman engaged very largely in commercial printing who used that strength at one time, who now used no more than half. He now used 40 grains of nitrate to the ounce of water, and made no other difference, but obtained equally good results. Again, Mr. Simpson and himself had recently called upon a gentleman whose name they all knew and respected; he referred to Mr. England. He, they found, was getting most perfect results with 40 grains, or less, because when the bath got low, he still only strengthened with a 40-grain solution. He made this difference, that he added one-eighth of methylated spirit to his solution; that was, he used 7 drachms of water and 1 drachm of methylated alcohol to 40 grains of nitrate of silver.

He entered into no theory on the subject, but simply stated his practice, and showed them his brilliant results. He prepared his own albumenized paper, and practically used $7\frac{1}{2}$ grains of chloride to the ounce. He used 5 grains of chloride of ammonium and 5 grains of chloride of barium, the latter being practically only equal to $2\frac{1}{2}$ grains of chloride of ammonium. If, then, with ordinary paper they could use much weaker baths than they had done, it was very important, and came more home to them than any question about the salting solution. And although it might be urged that any excess of silver used by recovery from the waste, it was certainly much better not to waste it and then have it to recover.

Mr. WALL said he had received a very brilliant print from Mr. Taylor, of Edinburgh, for which a 20-grain bath had been used.

Mr. HUGHES considered that the practice of men like Messrs. Sedgfield and Elliott and Mr. England was of greater weight and more important than that of amateurs.

Mr. HOWARD thought an amateur might well be embarrassed by the number of questions recently raised. It was almost as bewildering as the celebrated card trick. First the difficulties were referred to the tanning bath, then to the silver bath, then to the salting solution. He believed, however, that the paper itself was the basis. During the last 2 or 3 years the consumption of albumenized paper had increased four-fold; the result

was that a worse article was now sent out, not fit for the purpose, and hence the troubles which followed.

Mr. SIMPSON whilst agreeing with the admirable remarks of Mr. Hughes in the main, took exception to one or two points. In the first place, in regard to amateurs, whilst he fully admitted the weight which attached to the practice of such men as Mr. England, felt that the opinions and experiments of intelligent amateurs were often of great value and worthy of due consideration. In regard to the proportion of chloride, whilst it might be very difficult for manufacturers to state precisely the proportion a given paper contained, owing to the disturbing causes to which reference had been made, it might be very easy to state an approximation, and say whether from 5 to 7 grains, or from 12 to 15. As to the value of the knowledge, he might state that his friend, Mr. T. R. Williams, whose pictures everybody admired, was in the habit at one time of keeping a very weakly salted paper expressly for weak negatives, as securing the greatest amount of vigour. He handed round for the examination of members one or two charming prints he had that day received from Mr. Burgess of Norwich, excited on a 35-grain silver bath with 80 grains of nitrate of soda as recommended by a "Photographers Assistant," and one or two he had himself printed on paper excited 3 minutes on a silver bath containing 20 grains of nitrate of silver to the ounce. None of the prints were in any way wanting in vigour.

Mr. PRICE asked if Mr. Simpson's bath were old or new? Mr. Dawson had referred to the action of accumulated nitrates in an old bath.

Mr. SIMPSON said the bath was old, and doubtless contained an accumulation of nitrates of soda or ammonia.

Mr. HART showed some specimens on paper floated three minutes on 70-grain silver bath, and on 20-grain bath, containing 50 grains of nitrate of soda, the former had acquired a greater depth, with the same exposure, than the latter.

Mr. BLANCHARD said that the weak salting bath required, as he understood Mr. Harman, longer exposure. The result was really analogous to what most photographers were familiar with. They were in the habit of printing a weak negative in a slow dull light, in order to get vigour. Here the small proportion of chloride being less sensitive, was equivalent to a slow light, and it was easy to understand that it gave more vigour.

After some further desultory conversation,

Mr. SIMPSON said Mr. Williams had just mentioned to him that he continued to use a weakly salted paper for weak negatives, and that his experience confirmed the suggestions of Mr. Harman.

Mr. HUGHES thought that in referring to weak negatives a fresh issue was raised. Mr. Harman had recommended weak salting solutions for paper generally, without limiting them to that for weak negatives.

Mr. HARMAN had especially referred to weak negatives, in fact to the mass of portrait negatives developed with iron. With a hard negative he would prefer a heavily salted paper.

Mr. HART then exhibited and explained his Volumetric Apparatus.

A paper on "Glass Houses and Lighting the Model," by Mr. Parker, was announced for the next meeting. After votes of thanks, the proceedings terminated.

Correspondence.

SCENIC BACKGROUNDS IN TINTS.

DEAR SIR,—I have just had my attention called to an article in the PHOTOGRAPHIC NEWS of October 23rd, signed "R. A. S.," and which, if left uncontradicted, is calculated to do me serious injury in my business, as it boldly attacks a system which I adopt, viz., the employment of tints instead of greys in photographic backgrounds. "R. A. S." facetiously heads his epistle "A Dozen brief Hints to Portraitists." The word "Portraitists" would lead us to suppose that he meant professional photographers. Yet this cannot be, as he occupies two columns and a half of a journal devoted to the advancement of the science of photography, in telling us that which every one of ordinary capacity must have known before he had been an amateur photographer a week, viz.—that the background should be subservient to the figure—the shadow on the background and figure should

be on the same side—that the point of sight is opposite the lens, and that scenic backgrounds should be correctly drawn, &c. If, then, “R. A. S.’s” “brief hints” are intended for the infant photographer, why not write what he had to say so as to be within compass of the juvenile mind? But no, your intellectual contributor gets so confused with his own eloquence, as to be wholly unintelligible; for instance, he tells, in Hint No. 3, not to have our backgrounds painted in black or white, or anything approaching thereto; but by the time he has got to Hint No. 9, his taste appears to have undergone a radical change, and he is evidently of opinion that a background similar to a chalk-pit most artistic and suitable, for he tells us to have our backgrounds painted in black and white rather than in colours or browns. He further tells us, the argument against colours or browns is here in a nut-shell. The brown is warm, or, in other words, contains red, and so, where the colour is used thin, and where the colour is used thick, presents not only a contrast of light and dark visible to the eye, but a contrast of chemical action only visible in their action on the sensitized plate. These, then, are his clear, lucid, and comprehensive arguments against colours in backgrounds. I confess them to be wholly incomprehensible to me; it is to be hoped they are less so to the infant photographer.

In defence of colours, or rather tints (for “R. A. S.” does not seem to know the difference), allow me to say—and I challenge “R.A.S.” or any artist or photographer to prove to the contrary—that a charming effect is to be produced with tints in the hands of skilful men, not to be approached by greys, and that colour may be used with advantage and without losing any of the soft gradation of light and shade, in proof of which I send you copies of a few of my accessories, painted in tints and browns, together with one in greys by another artist. I say nothing for or against either, but wish each to stand upon its own merits. I would here say, for “R. A. S.’s” special enlightenment, that when a background is badly and gaudily painted, it is not the fault of the colours, but the manner in which they are used. “R. A. S.” in Hint No. 10, tells us, “when we use a background, to adopt the plan first introduced by Mr. Wall, viz., that of having the lower part of our background long enough to be stretched upon the floor of the room, and painted in imitation of earth,” &c. Now, in the first place, I hold that “R. A. S.” has no right to call attention to the productions of any one man, as it partakes too much the character of an advertisement. Secondly, Mr. Wall did not introduce the ground-cloth; it is a simple arrangement which would suggest itself to every one, and was sold by me when backgrounds were first introduced, with this difference—my ground-cloth was on a separate piece of canvas, so that one would serve for any exterior view. The background is allowed to hang over ground-cloth, which is slightly raised at back, so as to hide the joint, and at same time to give perspective to the ground. Mr. Wall’s ground is, however, part and parcel of the background, and this necessitates a fresh ground-cloth for every background—a very good arrangement for the seller, but not so for the buyer. A ground-cloth, painted in perspective, so as to match background and side-wings, was sold by me three years ago, and has been since patented. This arrangement gives the figure the appearance of standing bodily in the apartment, and the background some yards distant from the figure.

I must assert, in conclusion, that “R. A. S.” has supported no arguments in condemnation of tints, and that they have every advantage over greys I am in a position to prove. I hope, if “R. A. S.” is again allowed to occupy two and a half columns of a valuable photographic organ, which we have been wont to look up to for genuine information and instruction, he will confine himself to matters connected with photography. I feel constrained to say, the whole epistle smacks strongly of a disappointed rival; and I hope for the credit of others in the same business as myself, that “R. A. S.” will furnish his proper name in full.

Yours, dear Sir, most obediently, B. L. PHILLIPS.

“R. A. S.” condemned painting backgrounds in *colour*; Mr. Phillips defends painting them in *tints*. There is a great difference between the two things. Those of Mr. Phillips, painted in tints, have given very pleasing photographic results. Had they been painted in positive colours, they would probably have come out hard and unsatisfactory. The article in question was not intended to injure the business of any one.—Ed.]

Photographic Notes and Queries.

TONING AND MOUNTING.

DEAR SIR,—I send you a new formula for toning bath, which has the merit of simplicity, if it has no other; and I may add, I have never had a mealy print with it. It tones in about 20 minutes or half an hour to the colour of the prints enclosed. To 20 ounces of water, common or distilled, by preference the former, add 4 grains of Sutton’s neutral chloride of gold, which contains equal parts chloride of gold and sodium, so that only 2 grains of the precious metal are used. This is the simplest, most economical, and in every way the *best* toning bath I ever tried.

For mounting photographs, I know of nothing to equal gum tragacanth; to $\frac{1}{2}$ ounce of the gum, add two ounces of *cold* water, and in about 24 hours you have an excellent paste, which will keep good at least a month. A good plan is to keep a piece of blue litmus paper in the jar or bottle in which the paste is kept, so that if it turns acid it may be detected at once.—Yours truly, J. BURGESS.

Lower Goat Lane, Norwich.

[The prints accompanying this note are exceedingly beautiful. The paper, we are informed, was excited on a 35-grain bath, with 80 grains of nitrate of soda, as our contributor, a “Photographer’s Assistant,” has recommended. They leave nothing to be desired either as to tone or vigour. The two little girls are exceedingly charming. We have been experimenting with gum-tragacanth as a paste for mounting, and are glad to hear our correspondent’s good opinion of it. We shall have more to say on the subject shortly.—Ed.]

ELECTRIC LIGHT FOR PHOTOGRAPHY.

SIR,—I am much pleased to learn from W. N. B’s letter in your last number, that that gentleman has made experiments with the induction coil before, and that they were in so far satisfactory; it encourages me in the belief that with the considerably improved coils, and carbon points, in a vacuum, a splendid and cheap light may be obtained.

I beg to say that I shall very shortly make a series of experiments with the coils of a good Birmingham maker, and, along with the results of them, publish the address of the maker.—I remain, Sir, yours truly, AUGUST BUSCH.

14, Clifton Crescent, Asylum Road, London, S. E.

Talk in the Studio.

MORE PIRACY.—On Wednesday last, at Marylebone Police-court, Messrs. Spencer, Turner, and Boldero, linendrapers, of Lisson Grove, were fined for selling, without the consent of Messrs. Southwell Brothers, of 16 and 22, Baker Street, Portman Square, spurious copies of a photograph of Miss Ruth Herbert, as Diana, in the burlesque of *Endymion*; of George Vining, as Captain Hawkesley, in *Still Waters Run Deep*; also, a group copy of John Toole and Paul Bedford, in *The Flowers of the Forest*; in all of which there is a subsisting copyright in favour of Messrs. Southwell. The fines inflicted for three convictions were respectively 20s., 10s., and 10s., with 6s. the cost of the three summonses. Mr. Caldecott, of Praed Street, Paddington, was also convicted for selling copies of the same cards, and for each of the three offences fined 6d. without any costs! The cases were too clear to admit of any other issue than a conviction, but the magistrate, apparently to express his want of sympathy with the prosecution, saddles the complainant with the cost of obtaining the remedy the law provides, and couples his decision with insulting remarks. The complainants suffer a wrong in purse and reputation in having

their productions pirated and sold at 1½d. each. They proceed in the most simple and straightforward manner, without vexatious litigation or undue annoyance, to avail themselves of the provisions of an Act recently passed expressly to meet such cases, and Mr. Yardley, by the injudicious use of his judicial discretion does his best to render that Act nugatory. If this kind of thing be repeated it will call for remonstrance which shall be heard and must be heeded.

PHOTOGRAPHY AND FORGERY.—The Swiss, named Rinaldi, convicted some time ago of causing a forged copy to be made of an Austrian bank note by means of photography, recently appealed on two points reserved at the trial:—1st. Is a photographic impression on glass, such an engraving or making on any plate whatsoever anything purporting to be the note of a foreign prince, or an undertaking for the payment of money of any foreign State, as is contemplated by the statute. 2nd. Should the indictment not merely have charged the prisoner with an attempt or intention to engrave or make, and not with engraving or making? Mr. Metcalfe, for the prisoner, contended that as the photograph here was merely a "positive," and had to be transferred to a "negative" before it could possibly be engraved on metal, it was no engraving at all, but a mere evanescent shadow, which could not come within the Act. As to the second point, he urged that the police had seized their victim too soon, for he had only taken the first step towards engraving. He admitted that engraving on a glass plate was within the Act, but not only did the positive require to be converted into a negative, but the prisoner had directed the negative to be taken to an engraver, that the final engraving which was contemplated by the Act might be executed on metal. The Lord Chief Justice thought the conviction right. The case clearly fell within the very words of the statute. The process which the prisoner had adopted, put on a plate of glass the exact form of words, undertaking to pay money of a foreign state, more exactly than anything which the Arts had yet discovered. As to his being a victim, he was only victim in having lost an opportunity of deluging the country with the notes he intended to produce. Conviction affirmed." An amusing ignorance of photography appears to have been shown by the prisoner's counsel in speaking of the glass positive, or unintensified negative, as being an "evanescent shadow" requiring to be "transferred to a negative."

THE PHOTOGRAPHIC IMAGE.—Some recent experiments have recently induced Mr. Malone to suspend his opinion as to the metallic character of the Photographic Image. He blackened chloride of silver in combination with organic matter by light, and then mixing it with gelatine submitted it to the action of hyposulphite of soda, after which it was treated with hot nitric acid. It was not acted upon, however, as he had expected. He suggests that possibly each molecule of chloride of silver blackened by light still retains a minute core of unaltered chloride, protected from the action of light by the blackened surface, and that a voltaic action is thus induced which prevents the portion really reduced to the metallic state from being affected by nitric acid.

VERY RAPID COLLODION.—A correspondent of *Le Moniteur* gives the following:—"Prepare a concentrated solution of caustic potash in alcohol, and add of this one or two drops to each ounce of collodion. A slight precipitate will follow, and the collodion will become white. It can be used as soon as it is clear; but it does not retain the great sensibility confirmed more than a few days. It is desirable to excite in a small quantity of silver solution, as it has a tendency, with this collodion, to get out of order. It can be corrected, however, in the ordinary way."

CHAPPUIS'S PATENT REFLECTORS, for photographic purposes. These reflectors, generally used in dark warehouses, ships, apartments, &c., are now applied to photography.—P. E. Chappuis, patentee and photographer, 69, Fleet-street.—[ADVT.]

To Correspondents.

CORNISH GROUP.—Your negative arrived in a score of pieces, from none of which could we form any idea of the lighting of your sitter. A piece of card is useless to protect glass going through the post. Why have you blocked out all your side light? Send us a print, and a more detailed description of your glass-house, and we will try to help you.

E. B.—If you wish to protect every view of the house, you must register

the whole. Any view you do not register may be copied. 2. The paper may be used, but a blue tint would be better than green.

JAMES.—Intensifying with bichloride of mercury may be conducted in white light. 2. A few drops of strong ammonia in an ounce of water is sufficient to blacken the mercurialized film.

J. SIDDOES.—To convert a half sovereign into chloride of gold, proceed as follows:—Place it in a jar, and pour upon it 3 drachms of hydrochloric acid 1 drachm of nitric acid, and two or three drachms of water. Let this stand on a sand bath, or on the hob, so as to keep a gentle heat. In the course of a few hours examine, and keep adding more mixed acid every few hours until solution is complete. Now increase the heat slightly to evaporate the acids, but take care not to raise the temperature too much. When the acids are driven off the chloride will crystallize. It is not necessary to do this completely, however, as water may be added so as to make a solution of a definite strength. Half a sovereign will make about 86 grs. of chloride of gold. It is probable that some traces of silver and copper will be present, which might, by taking further trouble, be removed, but it is not of practical importance to do so.

SAOITARIUS.—One of the most useful manuals you can consult is that of Mr. Hughes; also "Bland's Practical Photography," and our ALMANAC. You would unquestionably gain immensely by a few practical lessons from a competent person. If you send us a stamped envelope we will send you the address of a good teacher with whom you may communicate as to terms. We cannot give you any better formula for the use of formic acid than those which have recently appeared in our pages. 2. We prefer neutralising and sunning to boiling the bath. There is room for improvement in your card.

YOUNG PHOTO.—On the whole the ammonia-sulphate of iron possesses the balance of advantage chiefly because it has less tendency to peroxidize. 2. The purpose of acid in the developing solution is to restrain the reduction from being over-rapid, and thus prevent fog, &c. Citric acid is much more powerful in restraining than acetic acid. The kind of acid used modifies the character and colour of the reduced image. 3. A stop is never used between the lens and ground glass, as it would cut off part of the image. It is used between the front and back glasses of a lens, and the rapidity of action is governed by the size of the aperture. 4. Whatever size of view your camera will take, it will take the size in portraits. You have got hold of some imperfect and erroneous idea. 5. Many articles on the solar camera have appeared in our pages; the most complete as a description perhaps appeared in No. 75.

QUEER.—The spots are caused by imperfect fixation from the hypo being too weak or the prints not properly immersed: very probably air bubbles have prevented perfect action.

FOGGO.—The best developing solution for producing silvery white positives is that of protinitrate of iron, which we have repeatedly given and which we shall repeat in our forthcoming ALMANAC. We presume that the enamelled iron plates are kept by various dealers; but we do not know of any especial house.

B. MENA.—The lens you have is not suited for card portraiture. The only mode of securing definition at the edges with it, is by using a small stop. We cannot answer your other question here. Send us a stamped envelope and we will write. Your card is a little short of exposure and lacks in definition. The printing is pretty good.

M. WILLETT.—The letter was duly forwarded.

E. M. T.—Some samples of paper are very prone to turn red in the hypo; when such is the case your only remedy is to tone deeper. It is sometimes the fault of the negative, which, being thin, does not permit sufficiently deep printing to give black tones. You need not fear being laughed at. We see nothing comical in persons wishing for information: there was a period in the history of all men when they were ignorant of what they afterwards knew. The last remark is so much of a truism or platitude that it almost sounds absurd, nevertheless, many persons are constantly forgetting it.

PHOTO (Tainton).—You should have stated what your present formula is when you wish for some improvement upon it. See our first article. If you do not glean what you want, write to us again.

WILLIAM THOMPSON.—We do not know of any effectual plan of restoring faded photographs. Several methods have been proposed; but so far as our experience is concerned they are uncertain and unsatisfactory. 2. There is no special work on the albumen process. Many articles on the subject have appeared in our pages. 3. Our ALMANAC will be ready in a few weeks. A varnish of india-rubber solution will probably make the calico light tight.

M. O.—Yours appears to be a very hard case, and if correctly stated, you are the victim of heartless and dishonest conduct. We do not see how we can help you, as you have entered into a foolish bargain; you have bound yourself to hard conditions without binding your employer to any. He can still hold you to your conditions, and at the same time turn you adrift. Nevertheless he will not have the hardihood, we think, to prevent you getting employment wherever you can.

PAPER DRAPER.—We do not remember any such advertisement, nor quite understand the meaning of the term. If you can explain more fully what you mean we shall have pleasure in helping you.

SUFFERER.—We do not know the name or address of Nemo; but have sent your letters to his agent, who promises they shall receive attention. Several Correspondents in our next.

PRIZES OF THE SOCIETY OF ARTS.

Is the list just issued of subjects for premiums to be distributed by the Society of Arts, during the sessions 1863-4, and 1864-5, are several entries to which we desire to call the attention of photographers. Despite all the arguments to the contrary which have at times been urged, and despite the petty jealousies and discontents which sometimes arise out of the awards, the system of prize-giving is incontestably a stimulus to emulation and competition, and these to improvement and progress. The premiums offered by the Society of Arts have been, in times past, productive of much good, from which the public at large have reaped solid results; and we do not doubt that the prizes offered in the list just issued will materially aid in giving point and direction to ingenious effort and inventive energy in the coming sessions. Various improvements and desiderata in photography, and the allied arts, are set down for prizes. The subjects are, as might have been anticipated, chiefly those improvements in photography in relation to ornamental purposes and to economies; the processes desired being such as are of the utmost importance in themselves, and well worthy the best energies of the ingenious photographer. We shall look with much interest for the issue, and hope that a brisk competition will be followed by the most perfect results.

The subjects for which the Society's medal is offered are as follows:—

PHOTOGRAPHS ON ENAMEL.—For the best portrait obtained photographically and burnt in in enamel.

PHOTOGRAPHS ON CHINA.—For the production of a dessert or other service, in china or earthenware, ornamented by means of photography and burnt in from an impression obtained, either directly from the negative, or from a transfer from a metal plate obtained directly from the photograph.

PHOTOGRAPHS ON GLASS.—For a table service in glass ornamented by means of photography, under similar conditions to the above.

PHOTOGRAPHS ON WINDOWS.—For the production commercially of ornamental glass for windows by means of vitrified photographs.

There are many other subjects for which prizes are offered which may interest the chemical and photographic experimentalist, such as a rapid means of reproducing designs for calico printing, in which it is probable photographic engraving and block-printing may be found useful; for a cheap spectroscope; for a simple and efficient dialysing apparatus; substitutes for albumen, &c. For details regarding these, we must refer our readers to the Society's published list.

We subjoin the conditions of competition which it will be seen are wide and liberal, taking no advantage of any kind of the competitor, but affording him the fullest opportunity of deriving the fullest profit, as well as honour from his invention:—

Patented inventions are not excluded from receiving the Society's awards.

The Society is willing to receive communications on subjects not included in the following list, but in all cases expressly reserves the power of rewarding any communication according to its merit, or of withholding the premium altogether.

The degree of originality and extent of suggestions for improvements will have material influence on the adjudication of the award.

In all cases a full account and description of the invention for which a premium or medal is sought must be sent to the Society.

All communications must be written on foolscap paper, on one side only, with an inch and a quarter margin. They must be accompanied by such drawings, models, or specimens as may be necessary to illustrate the subject. The drawings should be on a sufficiently large scale to be seen from a distance when suspended on the walls of a meeting room.

In regard to Colonial Produce of all kinds, it is absolutely necessary that a certificate from the Governor, or other qualified person, should accompany the samples sent to the Society, certifying that they really are the produce of the particular district referred to. The samples should be sufficient in quantity to enable experiments to be made, and an opinion to be formed of their quality; and it is desirable that the cost price in the district from which they are forwarded should be given. In every instance the probable extent of supply, with the average yield, if cultivated, and whether similar articles have hitherto been exported from the colony or not, and in what quantities, should be stated.

All communications and articles intended for competition must be delivered, addressed to the Secretary, at the Society's House, free of expense, either on or before the 31st of March, 1864, or on or before the 31st of March, 1865, except where otherwise stated. In the first case they will be considered during the session 1863-64, in the second case during the session 1864-65. This restriction, as to the date of receipt, does not apply to articles of colonial produce, in respect of which this list is valid until 31st December, 1865.

A communication rewarded by the Society, or any paper read at an ordinary meeting, will be considered as the property of the Society. Should the council delay its publication beyond twelve months after the date of its being rewarded or read, the author will be permitted to take a copy of the same, and to publish it in any way he thinks fit.

Unrewarded communications and articles must be applied for at the close of each session, between the third Wednesday in June and the last Wednesday in July, after which the Society will be no longer responsible for their return.—By order,
October, 1863. P. LE NEVE FOSTER, Secretary.

PHOTOGRAPHIC PROGRESS.

AMONGST the many signs of the prosperity of photography and of its growing and extending importance, we are glad to record the establishment of photographic societies in places where, until recently, nothing of the kind existed. A photographic society is at the present in course of being established in Berlin. A provisional committee has been appointed to make the preliminary arrangements, and to invite the leading photographers of the city to a general

meeting for completing the organization. Amongst the members of the provisional committee we are glad to find the name of Mr. J. W. Osborne, who is prosecuting his photolithographic experiments in that city. The other names are those of Dr. Vogel, and Messrs. Beyrich, Günter, and Suck. We hope shortly to record the further progress of the society. A photographic society has recently been established in Spain, and a journal entitled *El Propagador de la Fotografía*, established. In Italy, the new photographic journal established a few months ago, entitled *Il Camera Oscura*, is, we understand, progressing satisfactorily.

In the Southern quarter of the globe, we regret to say, matters do not look so satisfactory. The *Hobart Town Weekly Times*, from which we quoted, some months ago, an announcement stating that a movement for the establishment of a society was contemplated, informs us in a recent number of the complete failure of all attempts to excite a public or co-operative spirit amongst the photographers of Tasmania. The Editor of the Journal to which we have referred, set aside a column of his paper for the purposes of photography, inviting letters, articles, discussions, &c. He now gives the matter up in disgust. He has himself supplied a series of articles on interesting photographic topics; but has not received, during the four months which have elapsed, a single communication of any kind, good, bad, or indifferent. For the present he bids his photographic friends adieu, with the statement that journalism of any kind, without encouragement, is very uninteresting, but scientific journalism is, under such circumstances, simply unbearable.

ON THE TANNIN PROCESS.

BY W. WARWICK KING.*

As this process is not one of my own discoveries, I do not intend to say that it is certain, but speaking as one who has tried it with comparatively large plates (which are surer tests than small ones), I can safely say that I believe it to be nearer certainty than any other of the dry processes, and decidedly more simple. Every dry-plate photographer must acknowledge the value of Major Russell's work on the Tannin Process, though its usefulness is much impaired by the want of an index and marginal notes; but for my own use I have been largely indebted to my friend the Rev. J. C. Browne, who has practised the process with great success.

Having but little time for photography, I am unable to experimentalize; but as some encouragement to those similarly situated, I beg to offer a few observations, not that I can hope to communicate any novelty, but simply to place on record my own experience. Valuable as theory is to the art in general, yet more valuable to its ordinary followers, is practice, and if members would only give the results of their practice, or make notes of anything which they have observed in the course of their work, and communicate those notes to a society at one of its meetings, in the shape of a paper, instead of writing letters to the journals, I feel that much good would be done. I will now come to the subject for our consideration this evening. The plates must be cleaned with the utmost care. I have traced nearly every defect in the process to dirty plates. I discard gelatine, or any preliminary coating, because its application is troublesome, and only tends to complicate the process. We may rest assured that any addition which is not of positive good is a step in the wrong direction. The more we simplify a process the better.

I use Thomas's bromo-iodized cadmium collodion. I prefer it newly iodized—say, three days; and his bath, which is 30 grains, and neutral. I have worked with a bath containing 25 grains to the oz., but think the greater strength safer. It greatly conduces to the photographer's peace of

mind if he knows his preparations are correct. Having coated the plate as usual, wipe off with the hand any steam which has collected on the back of the plate, or the circle made by the pneumatic holder will appear in all the subsequent treatment. Dr. Kemp says, use a cloth for this purpose, but the said cloth is apt to produce fluff, which finds its way into the bath, and must, when there, be detrimental. Let the plate remain in the bath till all oiliness is removed, then immerse it in distilled water in a glass dish, moving it up and down occasionally till all oiliness disappears. Let it remain in the dish for 3 minutes. Then wash it well back and front under a tap for three minutes longer. Then swill with distilled water, and drain slightly. It is advisable to keep a small basin of water at hand wherein to dip the fingers after they have come in contact with nitrate of silver. This will prevent stains at the corner by which the plate is held. If any red stains appear, reject the plate at once; but if not, filter through two folds of fine muslin enough to cover the plate of

15 gr. tannin,

1 oz. aq. dist.;

Throw away the first portion, and then pour on a second, allowing it to remain a minute or two; then stand the plate up on one corner to dry, resting on clean blotting paper; never use the same portion twice. (A funnel with the stem broken off, leaving only the bowl, will be found very useful in filtering into measures). I generally mix the tannin solution eight hours before use. Any tannin seems to produce good results, but I always keep some which I procured from Mr. R. W. Thomas, because it dissolves immediately, and is perfectly clear without filtration. This is handy in the event of my requiring any tannin for immediate use. While speaking of tannin, I must name one precaution, that you do not let a drop of solution fall upon the glass while it is in the distilled water dish, or a spot will be produced which cannot be removed. The plate may be left to dry spontaneously. Major Russell says that the sensitiveness is increased by drying up to a certain point, and beyond that being diminished again; but I have found on looking at my plates the morning after their preparation that they are not dry; and then the placing of a stone jar filled with hot water in the drying box will cause them to dry rapidly without producing any ill effects; or the stone jar may be put in the box directly after the plates are stood up to dry, without, as far as my observation goes, sustaining the slightest injury. The plates, when dry, should present a polished surface. They are then so far good, but the surface must not be touched with the fingers, or a mark will be produced which cannot be got rid of.

With regard to the exposure, I cannot say that it is more rapid than the other dry processes. I find the average to be about 8 minutes in the spring and 20 minutes in the autumn, with a Grubb lens, for 9 by 7 plates, one-third inch aperture, 12 inches focal length for an ordinary subject, such as a stone building without any very dark trees adjacent. I always prefer to see something of the image before development, as then I know that, with care, subsequent operations will go on well. Before developing, varnish the edges of the plate with a solution of white wax dissolved in benzole; this will prevent the film from detaching itself from the glass. When this is done, place it on a levelling stand, and spread distilled water over the plate by means of a glass rod; let the water remain on for 3 or 5 minutes according to the temperature, which should not be lower than 60; then apply the developing solution,—

Pyrogallic acid... .. 2 gr.

Aqua dest. 1 oz.

Add thereto, according to the size of the plate, 1 drop of

Nitrate of silver 10 gr.

Citric acid 10 "

Aqua dest. 1 oz.

to each drachm of the first-named solution. Pour on and off till all the detail is well out; when this appears, inten-

* Read at the North London Photographic Association, November 15.

sify by adding a few drops of a second solution of nitrate of silver:—

Nitrate of silver	10 gr.
Citric acid	40 "
Aqua dest.	1 oz.

This strong acid solution will keep the developing solution clear during the intensifying. Where the image is sufficiently intense, wash thoroughly, and fix with—

Hypo	2 ozs.
Water	4 ozs.

Lastly, let running water from the tap fall on the plate for ten minutes, to remove the hyposulphite of soda.

One is apt to over-intensify, but I have found that a saturated solution of hypo will reduce the intensity, while that which I have given will not.

As to the keeping quality of the plates, I can say that they do not seem to deteriorate with exposure five weeks after their preparation, and may be developed a fortnight after exposure.

Before concluding, I will give a few hints to those about to take their cameras to the North of Europe:—

1st. Avoid the concertina form of body for the camera, as that contrivance harbours dust. Mr. Kinnear's original idea of velveteen, or something of that kind, is far preferable.

2nd. Pack your plates in grooves of cartridge paper; then in thin gutta-percha; then in sheet lead; and finally in brown paper. They will then travel safely, and not take up much room.

3rd. Do not take new apparatus to Denmark, or the Custom House officials will think you want to sell or patent it. You will meet with no difficulty whatever in Sweden, the enlightened rule of the government permitting all scientific instruments to pass free of duty, and you are treated with the greatest courtesy by the Göteborg Customs' officials; but it is otherwise at Copenhagen. There the Customs' officers seem to have taken a lesson from the Prussian officials, for they stopped my camera, suspecting and suggesting things which never entered my mind, and made themselves objectionable in every way. Their conduct will account for your having the paper now read instead of one which I hoped to have given you this year, and still hope to read next year, on a photographic trip in Denmark; for although the country is flat, there is much that would interest the photographer, archaeologist and artist.

A TRIBUTE TO THE AMATEURS.

BY MR. JABEZ HUGHES.

IN reference to the two divisions of photographers—the professionals and the amateurs—it cannot escape notice that the former often look on the latter with jealousy, and sometimes spice their remarks on their amateur brethren with unnecessary illiberality.

During the discussion at the last meeting of the South London Photographic Society, some words fell from me which, judging from the reply of Mr. Simpson, were held to be of this ungenerous nature. I express my regret that my words bore that interpretation, as my views are of quite an opposite nature. Although the wide-spread and extensive practice of the art depends on the professionals, yet these must never forget that all the original discoveries, great improvements, and marked advances are made by the amateurs. Who formed the first photographic society, and established the first photographic journal? The amateurs. They formed the bulk of the members, and for many years were the exclusive managers, and remain so almost yet. The provincial societies principally rely on the amateur element. The bulk of the papers read at societies, and of communications sent to the journals are by amateurs. Who introduced the present method of so-called alkaline gold-toning? Mr. Waterhouse, an able amateur of Halifax. Who invented the ammonio-nitrate method of printing? The

veteran amateur Dr. Alfred Taylor. Who even discovered the present collodion process but a calotype amateur, Scott Archer, assisted by two other well-known amateurs, Dr. Diamond and the late Mr. Peter Fry. Some time previously, two professionals, one a calotypist and the other a daguerreotypist, Mr. Bingham and Le Gray, used the material, collodion, and made nothing of it; but the amateur, Scott Archer, and his friends matured the process almost as it now stands. Of the few improvements made in it, from where have they emanated? The use of protosulphate of iron was made known by that veteran amateur, Robert Hunt. Dr. Diamond and Mr. Ellis discovered the developing powers of protonitrate of iron. A French amateur, Le Moync, brought out cyanide of potassium, and Sir John Herschell hyposulphite of soda. The use of bichloride of mercury, to make a white positive or a dense negative, was taught by Scott Archer.

He also invented the first camera to take pictures with in the open air. Formic acid was first made known by the Rev. Lawson Sisson, and pyrogallic acid was introduced by Mr. Archer. Of bromo-iodized collodion, the earliest published account is by the late Mr. Berry (then of Apothecaries' Hall, Liverpool), in 1853, and is described in the first paper read before the Liverpool Photographic Society. Plain bromized collodion, as recently introduced by Major Russell, had its early advocates in Mr. Crookes, M. Laborde, and Sir John Herschell.

The various modifications of the collodion process seem all to have originated from the amateurs. The first, though not successful, preservative process emanated from Messrs. Spiller and Crookes. This was speedily followed by the more practical honey process of Mr. Shadbolt, a process long a favourite one, and still practised by many. Then followed Mr. Llewellyn, with the oxymel, and Dr. Hill Norris, with the gelatine processes.

To glance at the numerous dry processes, commencing with Dr. Taupenot's collodio-albumen and Mr. Fothergill's, down to the labours of Major Russell in his tannin process, would only be to name a long list of amateurs who have more or less distinguished themselves in aiding photographic progress.

In vain we look for any original impulse from the professional fraternity.

Even in the matter of lenses, witness the elegant, and now universal, method of introducing the diaphragms. This was invented, not by a professional, but an amateur—Mr. Waterhouse; and recent testimony goes to show that the essential part of the triple lenses is due to the suggestion of Mr. Rothwell.

With all these facts before me, I could not treat lightly the labours of the amateurs.

Upon second consideration, however, it is not to be wondered that the impulses forward should emanate rather from the amateur than the professional. The former pursues the art for *pleasure*, the latter for *profit*. The one can try all manner of experiments, and whether he succeed or fail he secures his object—agreeable occupation. The professional, however, has all his energies directed to make things pay. He has too much at stake to speculate. He chooses the safest way. He is the true conservative, and when he gets hold of anything that works passably well, changes with reluctance. If an amateur experiment with a new toning bath on a batch of perhaps half-a-dozen prints, and fails, well, the loss is not great, and he gains in knowledge and experience. But the professional has his batch of perhaps six hundred; and if he fail, the loss is something considerable, to say nothing of the interruption of business. Many an experiment apparently succeeds from the limited nature in which it is tried. Amateurs' experiments are nearly always necessarily on a small scale. For this reason a distinction must frequently be drawn between their results and the professional man, who proceeds in an extensive manner. If my amateur friend tells me that I need not use my sensitizing bath for my albumenized paper so strong as 80 grains per ounce; that he is convinced by his experience

that 40 grains are quite enough, I, who believe in strong baths, may well shake my head and say that, "Your experience is too limited for me to take you for a guide. You sensitize perhaps two sheets per day on your bath, and that does not materially weaken it; but I may sensitize 50 sheets, and this materially alters the matter."

It was with these impressions that I drew a distinction between the conclusiveness of the experiences of such gentlemen as Mr. Taylor and Mr. England. Though both of them were right in using a weak silver bath, yet it is almost unavoidable not to attach more importance to the superior conclusiveness of the one gentleman's over the other. One practises on a very much larger scale than the other, and whether the plan will succeed on a large scale is exactly the point in question.

The advance of photography is something like the progress of an army. The main body keeps in safe marching order, while the more daring and adventurous are the pioneers who lead the way—rushing here, feeling their way there; always skirmishing, often retiring, but eventually succeeding in finding new tracks and safe paths for the main body to securely pass along.

In this way I look on each section as performing its own allotted task, the united result being the advance of the art.

JOTTINGS FROM THE NOTE-BOOK OF A PHOTOGRAPHER'S ASSISTANT.

No. VI.

ALKALINE TONING SOLUTIONS CONSIDERED.

TRADITION informs us that a certain philosopher, named Frankenstein, with wondrous skill and perseverance, gave existence to a clay-constructed monster, that subsequently proved an ever-linging source of terror to its wretched creator. In modern times, a clever photographer, Mr. Waterhouse, with praiseworthy motives, brought into notice a pigmy, whose mischievous pranks have proved a grief-yielding plague to thousands. Like the god of love, it wounds each Telemachus that attempts to fondle or press it to his bosom.

When the gentleman before alluded to introduced his new method of toning, he attached to the solution a quality which should have been shorn of absolutism ere it was so universally admitted in the photographer's vocabulary, for never was a greater error conceived than that which demands alkalinity in solutions intended to impart satisfactory tones to sun prints, for under such unlimited conditions unfailling results may be pronounced a simple impossibility.

When a surface of reduced chloride of silver is submitted to the action of a strongly acid gold solution, a decomposition ensues, that proves the substance of which the print is composed to be the disturbing cause, because, in the absence of such influence, gold in solution will remain undecomposed for any length of time, when associated with a portion of free acid.

Chemical decomposition is produced by superior affinities. Chloride of gold derives its three equivalents of chlorine from the hydrochloric acid, to whose biting influence the metal has been exposed. If a portion of chlorine is removed, a way is opened for a fresh attack, if any acid is present, for chemical laws are imperative, and the substance last named can remain quiescent only when the gold holds in combination its proper quantum of chlorine which it seems to retain with a very unwilling grasp; consequently, the superior attractions possessed by the silver cause a speedy separation, and the chlorine immediately proves its gratitude by exercising its devouring propensities on its liberator, weakening the print and imparting a false colour, which dissolves out in the hypo bath. The change produced by the attack of free acid on the subchloride of gold would be difficult to determine, but that it assists decomposition may be proved by the fact that its presence causes toning action to move in proportion to the quantity of acid the solution contains, whilst

with the same solution, minus acid, the gold, instead of imparting colour to the print, remains for a time inert, then gradually is precipitated, as has been proved a thousand times by all who have perseveringly adopted carbonate of soda toning. Free acid, whilst encouraging decomposition, doubtless lends its corrosive powers to aid the chlorine in demolishing the structure on which the gold should rest *when precipitated*; hence excessive bleaching, by destroying the foundation, removes all possibility of any molecular arrangement being effected by the colour-yielding agent that will produce anything more than an unsightly slatiness. From the above remarks it will be clearly perceived that a sample of gold containing but a slight trace of free acid, should, with a degree of over-priming, to meet the conditions required by the unassisted chlorine, impart to the prints a satisfactory colour.

The new toning bath proposed by Mr. Burgess admirably illustrates our meaning. He uses what he terms a neutral sample of gold; but from the fact that such an article can be produced only by an expensive method, we may safely conclude that a trace of free acid may be recognised, which is an assisting rather than a deteriorating quality, as we have before shown. With such a sample of gold as described by Mr. Burgess, the silver invites chlorine, but chlorine is in no hurry, as there is no large amount of acid to hasten its departure. It therefore takes its time, and separates too slowly for the exercise of much bleaching action; and whilst the gold deposits evenly, the good offices of the chloride of sodium is engaged in preventing an outbreak on the part of the noble metal, whose services remain uncalled for. With such a toning bath as recommended by Mr. Burgess, warm tones may be secured; but, for reasons to be recorded hereafter, we believe a black hue can be produced by the same solution only when a portion of the chlorine has been separated from the gold by heat applied previous to toning operations commencing.

But to return once more to Mr. Waterhouse. That gentleman perceiving the impossibility of toning satisfactorily with the then existing samples of gold, very sagaciously hit upon the true cause of failure; and this knowledge soon suggested a remedy, viz., removing the excess of acid by the addition of an alkaline substance; hence the name by which his solution was unfortunately introduced. We attach this last quality because, without due examination, we one and all rushed to a conclusion that the superior results were due to some change effected in the gold by alkalinity; and in this belief photographers may see the rock on which many a promising batch of prints has foundered, which loss would have been prevented had a trace of acid remained to steer them clear of the danger.

"Well," observes an intelligent reader of this "jotting," "what is here written is good enough in its way; but my solutions have worked well in the absence of an acid, which fact has been proved by the testing medium called litmus paper." The mode of testing referred to is a deceitful one. In our next paper we hope to show that a known quantity of acid may be present in a toning solution, and litmus paper will give no evidence of its presence. With respect to other toning formulas where soda forms the base of substances introduced with the gold, but little need be said of them by way of explanation. It will be readily perceived that acetic, phosphoric, and other acids, being more powerful than carbonic, are not so easily displaced, and for this reason they are unfit for toning baths intended for immediate use, but this disadvantage is atoned for by the keeping qualities it imparts to the solutions. In our next and last paper on toning, we shall treat somewhat further on this subject, and at the same time enter at length on the mysteries believed by many to exist in the process of lime toning.

PHOTOGRAPHIC RESIDUES.

BY JACOB EWING.

THAT the subject of photographers' silver and gold residues is now becoming one of importance, will appear from the

fact, that the Editor of the NEWS, ever ready to further the interests of photographers, has quoted and rightly recommended for adoption in this country, a method now about to be practised by a transatlantic speculator for the recovery of such *mis-named wastes*, and one which, if properly acted on, promises to give to the profession a means of avoiding much trouble and anxiety, at a stated per centage for labour expended.

This is to be looked upon as a step in the right direction, and if it be possible to reduce it to a practical bearing, and so do away with any doubts that may exist in regard to the intrinsic value, when taken away in a moist condition from photographers' places of business, and reduce the bother attached thereto, the plan would indeed be valuable. That such a scheme, or similar, is a desideratum is undoubted, as the photographer at present has great cause to entertain such unpleasing doubts, many strong cases serving to prove that he has been made the victim of some houses that advertise their willingness to *reduce* (and that too often with a vengeance) *photographers' waste*.

One case that happened lately, and now public, goes to prove this unfortunate fact:—A well known Scotch photographer, Mr. Macnab of Glasgow, having accumulated a large quantity of such residues in a dry chloride, paper ashes, &c., form wished to have it returned to the metallic state, and was naturally desirous he should get the full value of the metal which his collection represented, and being slightly imbued with the doubts before referred to, had a sample forwarded to a respectable London house, and was offered a return of two shillings per oz. for it, but having likewise sent a similar sample to a Glasgow refiner, he was surprised to hear from the latter party that he could have four shillings per oz. for it, or, in other words, he was offered £28 for it in London, he received £55 for it in Glasgow.

It is worthy of notice that the dry chloride gave a yield of within a fraction of 70 per cent., and the paper ash clear of carbon gave 71 per cent. The purity of the resultant metal may be judged from the fact that it was only some four pennyweights in the twelve ounces inferior to virgin silver. Then the charge was trifling; for example, for reducing 20 oz. of chloride, giving a yield of 19 oz.; 16 pennyweights, only cost 9s. 6d., and for large quantities it became much cheaper in proportion.

Now, without insinuating that any house would willingly defraud their customers, surely there must be an immense difference in the methods taken for the recovery of the pure metal. The plan adopted by Mr. Macnab was a wise one, and shows that photographers should be very careful to have their silver properly tested before sending large quantities to be reduced, as thereby they may effect a considerable saving, the quantity reduced for Mr. Macnab by the refiner (Mr. Wm. Coghill, Maxwell Street, Glasgow), amounted to over £120 sterling. We can thus see that our wide-awake Yankee friend, with his liberal offer and supply of apparatus, could yet manage a handsome income for his trouble, and yet afford to give to his customers a larger return than his enterprising friend on this side of the water.

PHOTOGRAPHY IN THE COUNTY COURT.

JNO. LOUIS V. SCHNADHORST AND HEILBRONN.

On Monday last, the 23rd inst., at the Westminster County Court, a case of some importance to the profession was heard.

The plaintiff and his wife sat for "Cartes de Visite," on the 30th of May, and now sued for 3s. 6d. balance due for portraits he alleged the defendants had failed to deliver in due course.

The plaintiff said that he had been abroad and unable to present his claim earlier, and urged that the remaining portraits had not been sent.

Mr. Heilbronu proved that the photographs had been duly delivered (partly to plaintiff himself at their studio,

and the remainder at his residence), by witnesses now in court, and erased from their books accordingly.

His Honour said that the defendants had made out a clear case, and observed that it was not at all requisite to take a written receipt for the delivery of photographs.

Verdict for the defendants, with costs.

RESEARCHES ON POSITIVE PRINTING.

BY MM. DAVANNE AND GIRARD.

TONING.

WE divide the numerous toning processes practised up to the present time into four classes.

1st. The so-called *acid toning*: that is to say, due to the employment of commercial chloride of gold, to which most frequently a certain quantity of hydrochloric acid is added.

2nd. Toning with neutral chloride of gold, due to the employment of the double chlorides of gold and potassium or sodium, recommended by M. Fordos.

3rd. Toning with protoxide of gold, characterized by the employment of the double hyposulphite of gold and soda, known to photographers as *sel d'or* or *Gelis's salt*.

4th. Alkaline toning, due to the employment of chloride of gold, most frequently a double chloride to which salts possessing a slight reaction are added, such as the bicarbonate, acetate, phosphate, and borate of soda. Into this category also enter those tonings in which the employment of chloride of lime is recommended, which, acting upon the pure whites of the albumen by the chlorine it contains, operates from the point of view of true toning only by the excess of lime with which it is charged, and so furnishing an alkaline bath.

To explain the true nature of toning in all these cases, we must, for each of them, estimate the relative proportions of gold and silver taken up by the proof toned, and compare them with the quantity of silver contained in a proof not toned, but prepared under similar conditions. In each process, we must also consider the case where the toning takes place previous to the fixing, and that in which the toning takes place after fixing, and repeat such experiment twice, varying the time of exposure, so as to give faith only to concordant results.

But this is not all—for considering that the picture is, according to the theory we have established, composed both of metallic silver and argentic organic matter, a kind of *lake* obtained by a combination of albumen, starch, gelatine, &c., with silver, and similar in all respects to the real lakes formed by colouring matters in textile fabrics—we have made parallel experiments upon papers simply salted and unsized, which, after exposure, contained almost only silver, and upon papers simply albumenized and not salted, that is to say, containing almost only argentic organic matter. From the resulting sixty-four experiments, we now give the numerical results and conclusions.

Let us first describe the method we always adopted. In each case, four half-sheets were carefully prepared, sensitized, exposed, &c. At the moment of introducing them into the toning baths, each piece was divided into two, one-half only has been toned, the other has been kept without toning, and as a standard of comparison. (We had satisfied ourselves by previous experiments that each half-sheet contained the same quantity of silver, and that we could give absolute confidence to this comparative stage).

The proof being finished, we placed in a large platinum capsule, a sufficient quantity of pure nitre, which we gently heated to fusion, then with a pair of pinchers seizing each piece of paper rolled up, we slowly burned them over the bath of melted nitre, in such a manner, that the heat was strong enough to produce a ready combustion, and yet insufficient to allow us to fear a volatilization of the silver. The cold mass was taken up by water, filtered and washed upon the filter with diluted acetic acid, to remove the considerable quantities of alumina, iron, and lime which arising from the ashes of the paper, would have prevented the fusion of the precious metals. The filters washed and dried, were afterwards passed into the cupel, the buttons of metal weighed, quartered when they were toned proofs, and the ordinary method departed from in employing successively nitric acid at 22 and 32 degrees.

Let us now proceed to study the first case that presents itself in our classification; that of toning with acid chloride of gold. The numbers we have obtained in the sixteen experiments made, are given in the following table. As to the calculations

from which we have deduced our conclusions, they have been established in starting upon the fact that in employing chloride of gold, Au³ Cl³, the latter, in the act of substitution, must theoretically transform it into chloride, and consequently be placed in such a condition that the last fixing may cause the three equivalents of silver to disappear, according to the formula—

which, consequently,

$$\text{Au } 2 = 196$$

must replace

$$\text{Ag}^3 = 108 \times 3 = 324.$$

1ST.—TONING WITH ACID CHLORIDE OF GOLD.

TONING AFTER FIXING.

Proofs upon Paper simply Albumenized.

Time of Exposure.	Numerical Order.	Numerical Results.	Results of Experiments.
2 Hours.	No. 1. Portion not toned.	Ag 0.121	0 gr. 034 of gold equivalent to 0.056 of silver, the portion toned (No. 2) should contain 0.121 — 0.056 = 0.065 of this metal; but experiment gave 0.059; in this case we find the proportion of silver 0.006 deficit
	No. 2. Portion toned.	Ag 0.059 Au 0.034 Ag + Au 0.093	
15 Minutes.	No. 3. Portion not toned.	Ag 0.049	0 gr. 012 of gold equivalent to 0.019 of silver, the portion toned (No. 4) should contain 0.049 — 0.018 = 0.030 of this metal; but experiment has given 0.028; in this case, therefore, we find the proportion of silver 0.002 deficit.
	No. 4. Portion toned.	Ag 0.028 Au 0.012 Ag + Au 0.040	

Proofs upon Paper simply Salted.

2 Hours.	No. 5. Portion not toned.	Ag 0.236	0 gr. 062 of gold equivalent to 0.102 of silver the portion toned (No. 6) should contain 0.236 — 0.102 = 0.134 of this metal; but experiment gave 0.123; in this case, then, we find the proportion of silver 0.011 deficit.
	No. 6. Portion toned.	Ag 0.123 Au 0.062 Ag + Au 0.185	
15 Minutes.	No. 7. Portion not toned.	Ag 0.076	0 gr. 017 of gold equivalent to 0.044 (of silver, the portion toned (No. 8) should contain 0.076 — 0.044 = 0.032 of this metal; but experiment gave 0.026; in this case, then, we find the proportion of silver 0.006 deficit.
	No. 8. Portion toned.	Ag 0.026 Au 0.027 Ag + Au 0.053	

TONING BEFORE FIXING.

Proofs upon Paper simply Albumenized.

2 Hours.	No. 9. Portion not toned.	Ag 0.154	0 gr. 028 of gold equivalent to 0.046 of silver, the portion toned (No. 10) should contain 0.154 — 0.046 = 0.108 of this metal; but experiment gave 0.092; in this case, therefore, the proportion of silver is 0.016 deficit.
	No. 10. Portion toned.	Ag 0.092 Au 0.025 Ag + Au 0.120	
15 Minutes.	No. 11. Portion not toned.	Ag 0.068	0 gr. 014 of gold equivalent to 0.024 of silver, the portion toned (No. 12) should contain 0.068 — 0.024 = 0.044 of this metal; but experiment gave 0.037; in this case, then, we find the proportion of silver 0.007 deficit.
	No. 12. Portion toned.	Ag 0.037 Au 0.014 Ag + Au 0.051	

Proofs upon Paper simply Salted.

Time of Exposure	Numerical Order.	Numerical Results.	Results of Experiments.
2 Hours.	No. 13. Portion not toned.	Ag 0.304	0 gr. 065 of gold equivalent to 0.109 of silver, the toned portion (No. 14) should contain 0.304 — 0.109 = 0.195 of this metal; but experiment gave 0.176; in this case, then, we find the proportion of silver 0.019 deficit
	No. 12. Portion toned.	Ag 0.176 Au 0.065 Ag + Au 0.241	
15 Minutes.	No. 15. Portion not toned.	Ag 0.115	0 gr. 036 of gold equivalent to 0.059 of silver, the toned portion (No. 16) should contain 0.115 = 0.059 of this metal; but experiment gave 0.042; in this case, then, we find the proportion of silver 0.014 deficit.
	No. 16. Portion toned.	Ag 0.042 Au 0.036 Ag + Au 0.078	

Thus, in all the preceding cases, the substitution of gold for silver has evidently taken place in atomic conditions; this regular progress takes place upon argentic organic matter as well as upon silver, and both before and after toning, and after short as well as after long exposure. Nevertheless, as the conclusions contained in the last column show, experiment in all cases shows a slight deficiency of silver; this deficiency is very evidently due to the acidity of the liquid, to the presence of hydrochloric acid in the toning bath; this acid attacking (independently of all toning) a portion of the silver, converting it into chloride, which the fixing salt subsequently removes; this observation explains the well-known maxim;—acid toning baths redden the proofs.

This mode of toning is regular and quick; it gives slightly red tones, but which are not disagreeable; but the great danger it presents is shown by the following; it removes more silver than is required by theory, and it diminishes the intensity of the proof in proportions which the photographer has not always the power to check. Moreover, if we compare the experiments Nos. 8, 12, and 16, made after exposure of a quarter of an hour, with the experiments Nos. 6, 10, and 14, made after exposures of two hours, it appears that the deficit of silver is more sensible in the case of short exposure than in long; in a word, it appears that under the dissolving action of the hydrochloric acid the half-tones suffer more than the deep blacks.

In conclusion, we cannot recommend this toning process, as photography is now in possession of a more advantageous one; still, in cases where it may be employed, for special works, the operator must print a vigorous proof, in order to compensate for the loss of strength caused by the hydrochloric acid.—*Bulletin de la Société de Photographie.*

A FEW WORDS IN REGARD TO LIGHTING OPERATING ROOMS FOR PORTRAITURE.*

THERE is probably no one department of photographic manipulation so disregarded, neglected, or perhaps as little understood among Americans—in fact, it may be said of all photographers—as the proper lighting of operating rooms; one of the principal causes from which result the great majority of poor, worthless pictures, which we find in every community.

This defect in many establishments does not arise from careless indifference in regard to the character of work produced, for nearly all have a desire for success which will remunerate the expenditure of time and capital, aside from the gratification of an honourable pride of reputation, not only with patrons, but in the profession. Many operators, whose knowledge of chemical manipulation is sufficient to enable them to produce passable, or even good work, are so little acquainted with a few simple laws of nature in regard to light, that their productions are almost invariably unworthy the name of pictures.

* *The American Journal of Photography.*

Let us, as physicians would say, make out a diagnosis of a few cases, and then seek for the remedies with which to produce our cures. First, A wants a sky-light operating room, which he designs as follows; size of room, 18 by 24 feet; height of walls from floor, 10 feet; north pitch of roof, and number of degrees, between 10 and 45; sky-light, 8 by 10 feet flush with roof; lower edge of light 2 feet from intersection of wall and roof, and 3 feet from end of room, &c. A's case is hard, though not an uncommon one, and his productions are a constant—provided they do not fade—advertisement of his own ignorance. His "pictures" are patches of intense light and shadow, which make very good caricatures of those who favour him with their patronage. All the high lights are *very* perceptible, and all, or nearly all, in the shadow are quite *imperceptible*. The light upon the forehead and brows is relieved (?) by the midnight darkness which reigns beneath the brow, nose, and chin. The great artist Sol, or his assistant A, has evidently turned off an unfinished work. The half-tones, which add so much beauty, seem to have been entirely forgotten, or put in with such violent contrasts that their beauty is much like a light under a bushel.

A's sitters call his pictures "flat," "chalk and ink," "don't look them," and they resolve to patronise his neighbouring photographer B.

A sits down to cogitate—wonders what the matter can be. He thinks that some change in his chemicals may reduce the high lights, and bring out the shadows. Tries it: result—anything but brilliant. After great and manifold trials, gets the blues, becomes disgusted with the business, concludes that he was not made for a photographer, and sells out.

B built his operating room after A's model; but his patrons being a little more fastidious than A's, often found fault with the blackened eyes, and ugly spot under the nose and chin, which his picture represented.

B, being a little more shrewd than A, had, after trial, consultation and study, sought a remedy by introducing a small window into the side wall of his operating room. This window for economy's sake must be small, besides which he feared a large window might give *too much* light. After this improvement he hoped to succeed. He did *partially* succeed in getting rid of those "ugly black places," and began to hope that all was right.

Alas for human hope! His sitters again began to complain. This time some of their pictures looking "as though they were dead;" others, "the eyes look so badly," still others, "no eyes at all;" and occasionally some one would persist in trying to make poor B believe that one side of his face was *not* very dark, and the other, *very* light; and some wanted to know what "those two *white spots* in the eyes were for?"

One lady would indignantly remark that her picture made her look like the fat woman at Barnum's, and another that her picture looked like a hatchet; some were too old, and *few* too young.

B is in a quandary and asks for advice, which we humbly offer; advice founded upon the experience, failures, and successes of fifteen years' practice, resulting in the ability to produce what friends, and we trust a majority of patrons, unite in calling first-class work.

Axiom—No one ever did or ever can produce *good* pictures by a badly arranged light. Consequently, *never* use a room for your sittings in which you cannot get a *good* light. If you own a badly arranged room, remodel it, or build another. If you are a tenant, make your landlord do it for you, or take rooms of one who will give you this one feature which you must have—a good light.

My own experience leads me to prefer a light for portraiture arranged, as near as may be, upon the following plan. For copying, a different arrangement will be found preferable, which may be explained in future.

The light or window should be at least five or six feet from the end of the room nearest to the window, but the better plan is to have the light midway of the side wall of the room, thus giving better facility for working both ways, which is

necessary very often in all large establishments, or those who prize uniform good result.

The operating room should be at least ten feet high, the other dimensions may be such as the size of work, instruments, capital, &c., may require and admit of. A room fifteen by thirty feet will answer for all the ordinary sizes and styles; for large groups, more room might sometimes, though seldom, be required. The window for such a room should be about ten feet wide, introduced into the side wall, within not more than twelve inches of the operating room floor, reach from that point to the intersection of the wall with the roof, and from that point it may follow the angle of the roof a sufficient distance to bring a plumb line from the upper edge of the glass to the floor, at least two-thirds of the distance across the width of the room, measuring from the bottom of the window near the floor. If the roof is nearly flat, sufficient rain-shedding pitch may be given, by raising that side or edge which is farthest from the perpendicular portion, or a ridge may be introduced into that same part, which we will call the roof of the skylight. Such ridge should be as light as safety will allow, as also should be the rail or beam at the intersection of the wall and roof portion of the window. If the window faces towards the north, use plain white glass, unless the prospect is an unpleasant one, and you can afford sufficient loss of light to shut it out with ground glass. If your window faces south, east, or west, finely ground glass will be found preferable to the plain.

In either case, never omit having curtains or some other subduing agent arranged over your whole window, so as to give you perfect control over the light. A very effectual method of accomplishing this is found in an arrangement of wires and curtains across (*never* up and down), your window both side and top. The curtains should not be more than thirty or thirty-six inches wide, and should be so arranged as to overlap each other a few inches, as shingles or slate on a roof. The wires can be arranged by stretching them from blocks fastened at each side of the window, in such manner that the rings on the edges of the curtains will slide upon them without any difficulty. Never make your operating room look like the deck of a man-of-war by attaching cords and rigging to your window curtains; such arrangements often get out of repair, and require considerable nautical skill, which is not needed by landmen photographers. A light wooden rod is the most convenient article for changing the position of your curtains, and can be gotten up quite tasty enough for the most fastidious. Very good curtains can be made of light blue unglazed muslin, or cambric, or some similar material; and if you want still greater control over the light than these would give you, it can be obtained by using two sets of curtains, one of light material, the other of dark or heavy, thus enabling you to shut off all light from any part of the window which you may choose. Other arrangements there are, such as coloured glass or wooden shutters, but the writer has never found anything so convenient and effectual as properly arranged curtains.

NEW PROCESS OF ENGRAVING.

[The following account of a new process of engraving is worth the attention of all those of our readers who are interested in the general progress of the fine arts.]

We have been commissioned by Mr. E. Vial (an eminent chemist of Paris) to direct your attention, as a *connoisseur* in the fine arts, to an important invention which he has made in the art of engraving, which virtually places the graver in the hands of the artist himself, so that his own most subtle touches are at once faithfully engraved on a steel or other plate, preserving the individuality and real feeling of each artist in precisely the same degree as his own painting or drawing would do.

This process admits of the following variations:—

1. The artist may draw directly upon the steel plate in either crayons, or lithographic, or other ink, and the slightest touch, as well as the broadest lines, will be *instantaneously* engraved in intaglio.

2. The artist may draw in crayons, or in lithographic or other ink upon paper, and the drawings can be transferred to the steel plate and engraved instantaneously.

3. The artist may draw with chalk, ink, &c. upon zinc, and the drawing will be faithfully engraved in relief.

4. The most elaborate engraving or lithograph can be reproduced on a steel plate in from ten to thirty minutes from a *paper proof*, without injury to the original.

The process is also equally applicable—

1. To the instantaneous engraving of calico-printing, embossing, and other rollers, either from designs drawn on the metal or on paper, or from lace or other fabrics placed in contact therewith.

2. To the instantaneous engraving or damaskeening of arms, cutlery, &c.

3. To *photographic* or *heliographic* engraving on steel, and to various other useful purposes where rapid, faithful, and economical engraving is required.

The rapidity of the process is truly marvellous, and the net cost is merely nominal.

The process has been very favourably spoken of by the French press, and has been witnessed and approved of by the most eminent savants, artists, and others in France, amongst whom we may refer you to M. Dumas, senator, member of the Institute, &c.; Marshal Vaillant, Minister of Fine Arts; Count de Nieuwerkerke, Superintendent of Fine Arts and Director of the Imperial Museums; Messrs. Goupeil and Co., and Messrs. Hachette and Co. (publishers), &c. &c. The latter are working the invention *commercially* in France.

We shall be happy to give you further information, and to show you specimens of the remarkable results obtained, on your favouring us with a call at your convenience.—We are, Sir, your obedient servants,
DAVIES AND HUNT.

NEW PHOTOGEN FOR OBTAINING PORTRAITS AT NIGHT.

BY M. MC A. GAUDIN.

As winter approaches it becomes necessary to think of the means of obtaining portraits at any hour of the day or night, especially in those places where the light becomes very weak. I have already pointed out the means which succeeded with me in employing a firework composition.

For some time past I have made use of a small furnace, placed under the chimney of my room, with which to obtain very high temperatures. Being on the ground floor, the chimney has a draught of nearly 70 feet, and as all the air of the chimney must pass through my furnace, the activity of combustion is very great. To obtain the largest fire possible, instead of coke, which cakes together, I use the graphite of gas retorts, such as is employed in galvanic batteries. On the first day the bars of my grate were burned and melted, and on the second day the little bars of iron which replaced them shared the same fate: then I placed some large iron bars at the bottom, and had, it might be said, no grate, making the combustible itself serve instead; so that when my furnace is in full operation, its ash heap is the seat of a vivid combustion which splendidly illuminates the lower portion of my room.

It is this that gave me the idea of a photogen for obtaining portraits at night, by adding a stream of oxygen to the air drawn through the furnace. When fed by atmospheric air alone, the light given forth is equal to a hundred candles, but with the addition of oxygen, it attains to a thousand candles.

To establish a photogen of this kind, the closed chimney of a room on the ground floor must be put in communication by means of iron pipes, with the furnace placed opposite a reflector of elliptical curvature. The furnace will be composed of a grate of refractory clay placed upon a cast-iron cylinder in two compartments; the internal cylinder serving for the passage of the flame and the enveloping cylinder being the reservoir of the oxygen gas which passes in through twenty small holes of one-tenth of an inch in diameter in front of the furnace. The grate will be protected by a lump of fire-clay, leaving at the side the oxygen enters a circular opening of four inches in diameter, by which the air of the apartment can flow in upon the combustible by the draught of the chimney, drawing with it the oxygen gas which escapes from the reservoir without velocity.

To obtain the oxygen without employing a gasometer, we place above the fire, in the grate, a cast-iron pot half filled with

chlorate of potassa mixed with its weight of oxide of manganese. This pot has a pipe connecting with a reservoir of oxygen by a flexible tube, and when it is exhausted of its gas it can be replaced by another.

From the operation of this apparatus there will result a very dazzling photogenic light proceeding from the illumination which will be at its maximum on the surface of the coal arranged dome-wise upon the clay grate, and receiving a reverberation from the cover. If the grate happens to melt, we must interpose between it and the coal some small flints, such as are found naturally rounded in the diluvium.

The cast iron pots for making the oxygen gas in, have a rim, and contain about three gallons. This production of oxygen gas is unattended by any danger, the pulverized manganese is intended to moderate the action of the liberation of the oxygen gas from the chlorate of potassa, which becomes very furious towards the end, because the chlorate first passes into the state of per-chlorate, and in the end this per-chlorate is decomposed with violence if the fire is not kept down. In the present arrangement the fireplace being distant, its effect is always regular, and the disengagement of oxygen is regulated by passing through a large number of large holes, and the last effervescence in the iron pot cannot take place except through a prodigious increase in the intensity of the furnace.

The fire is first lighted with charcoal, and the fuel is stirred from time to time, to throw down the ashes formed in small quantity upon the graphitic carbon in full ignition.

With such a photogen, giving the light of a thousand candles, the floor and walls of the room around the reflector being covered with light-blue calico, portraits may be obtained at night as quickly as in an ordinary glass room during the day.—*La Lumière*.

Proceedings of Societies.

NORTH LONDON PHOTOGRAPHIC ASSOCIATION.

THE usual monthly meeting was held in Myddelton Hall on the evening of Wednesday, the 18th inst., Mr. G. SHADBOLT in the chair.

The minutes of a former meeting were read and confirmed.

Mr. W. WARWICK KING read a paper on the Tannin Process, (see p. 566), and exhibited a number of fine negatives and prints.

Mr. SEELEY asked Mr. King if he ever was troubled with pinholes in tannin plates.

Mr. KING had met with them occasionally, but attributed them solely to dust.

Mr. SEELEY was disposed to attribute them to the accumulation of iodide of silver in the bath, as it was worst with the last of a large batch of plates.

Mr. King had used a bath for many plates in succession without meeting with spots except such as he could trace to dust.

A conversation on the keeping qualities of tannin plates followed, in the course of which,

Mr. G. CARTLAND, jun., of Eton, said that the Rev. Mr. Carter Brown gave him two stereo tannin plates last Christmas, and he did not expose them until a week ago, when they yielded good negatives.

Mr. SHAVE had kept Fothergill plates 12 months, and then got good pictures. He asked Mr. King if he got as much detail in foliage with tannin as with Fothergill.

Mr. KING thought quite. In answer to another question, he said he kept the plate in the nitrate bath five minutes.

After some desultory conversation on the influence of temperature, the use of citric and acetic acids,

The CHAIRMAN said that a very low temperature was always detrimental to chemical action, and scarcely sufficient attention was paid to this in development. It should be borne in mind however, that if a high temperature were used, and acetic acid employed at the same time, a larger quantity would be necessary owing to the evaporation. He asked Mr. King how long after exposure he had kept the plate before development.

Mr. KING: Not more than a fortnight.

Mr. SEELEY could not keep them after exposure more than two days, and the longer they were kept the worse was the negative. It was weak, foggy, stained, and poor when the plate was kept.

The CHAIRMAN said that, in working the honey process, he

remembered that whilst plates were fresh they were perfect; in a short time a reaction was set up which gave irregular results, but after a longer time keeping the reaction was complete and and the picture was clean, but required longer exposure.

Mr. KING had found no difference from one day to fourteen. He was keeping some now for a longer time to try them.*

Mr. SEELEY said that, unexposed, they would keep indefinitely.

Mr. HILL thought that bad keeping was due to the presence of free nitrate.

The CHAIRMAN thought that where keeping caused irregular development, it was owing to development having set up spontaneously.

Mr. SEELEY used gelatine as a preliminary coating.

Mr. KING used no preliminary coating.

The CHAIRMAN thought that this might possibly account for the discrepant experience, as the gelatine itself might form a compound with the nitrate of silver sensitive to light.

Mr. SIMPSON remarked that all organic compounds of silver were liable to spontaneous decomposition.

A conversation followed, in which some doubt prevailed as to whether Major Russell said that gelatine plates would keep well, if prepared in quantities ready for use. Mr. Simpson remarking that both views were right. Major Russell said that plates prepared with simple gelatine did not keep well, but if the gelatine were iodized they kept better.

A conversation followed on the appearance of the image before development, which Mr. King always expected to find if the exposure were correct.

Mr. SEELEY said he always regarded it as a sign of over-exposure. He never found it, except when a bromide was used as well as an iodide. Mr. King's exposures were very much longer than he had ever given. He would himself give, with a view lens of 11 inches focus and $\frac{3}{8}$ ths stop, three minutes in a good light.

Mr. KING had never worked so quick, nor did he think that an under-exposed plate would give a good negative with any dodging in development. An over-exposed might be preserved with care in developing.

The CHAIRMAN observed that Major Russell was far too close an observer, and too careful to give instructions for having an under-exposed picture in development, without sound reasons for his conviction that this was possible.

Mr. HILL said he did not believe it was possible to over-expose a dry plate. He had exposed a picture twice without the slightest injury.

Several members said that over-exposure would give a weak sky.

The CHAIRMAN related a curious experience in exposing a plate twice, tending to show that light could undo what it had done.

After some further conversation, Mr. G. DAWSON said he thought much of the uncertainty which existed in relation to the tannin process arose from photographers being ignorant of the materials with which they were working. They frequently took any collodion that came to hand, and although Major Russell had said the collodion did not matter much, in his experience it was very important, and he found that many otherwise good collodions would not answer for that process, and others which might be used required preliminary coatings on the plate. He had found that for pyroxyline a modification of Hardwich's formula gave the best results. The formula which after one trial he found gave the best results was as follows:—

Sulphuric acid (commercial oil of vitriol)			
sp. gr. 1.840 by measure	36 ounces
Nitric acid sp. gr. 1.450	12 "
Water	8 "
Best cotton	800 grains

The cotton was immersed at a temperature of 155 Fahr. This would yield 1,000 grains of pyroxyline, and by its yielding this weight, he tested its exact suitability for the purpose. The collodion was then made as follows:

Ether sp. gr. 725	4 drachms
Alcohol sp. gr. 805 to 810	4 "
Pyroxyline	5½ grains
Iodide of cadmium	1½ "
" ammonium	1½ "
Bromide of cadmium	2 "

With this collodion he could work on plates 14 inches square without any substratum or preliminary coating. He coated and excited in the usual way, using then a 10 or 15 grain tannin solution, and he had absolute certainty in the results. Before developing he ran an edge of Sohnee varnish round the plate for about the eighth of an inch, and lost no films. In dry collodion he thought that certainty was of more importance than rapidity; and this process was not very rapid,—not so rapid as some of Major Russell's results. He found some uncertainty with the process Major Russell had recently recommended. Using the same collodion with no iodide but 7 or 8 grains of bromide of cadmium, exciting in a 60-grain bath for 10 minutes, draining five minutes before washing; then well wash; then immerse in salt and water; then wash again in common water; then apply a 10-grain tannin solution, and finally wash again with distilled water, and dry. With these he found indications of great sensitiveness, but a great tendency to fog, perhaps only one plate in six yielding a good negative. He developed with carbonate of ammonia and pyrogallic acid, as directed in Major Russell's book. Major Russell himself thought very highly of this method, and in his hands it gave beautiful results; but in his (Mr. Dawson's), he had only obtained one or two at all presentable pictures, although it was very rapid. He thought many failures were due to imperfect washing; they could not wash too much, and an ill-washed tannin plate was less sensitive than a well-washed plate. The use of a bromide was very important; one grain to the ounce gave a great improvement upon none; two grains an improvement upon that; and three grains seemed to cause a falling off again. He agreed with Mr. King on the importance of removing complications and securing simplicity.

The CHAIRMAN thought Mr. Dawson scarcely understood Major Russell as to the use of any kind of collodion.

Mr. DAWSON said it was probable that with almost any collodion a picture could be obtained; but it was impossible with some samples to avoid crapy lines, and with others to prevent the film splitting from the glass.

A conversation on certainty followed, in which Mr. King said that as a rule he could take out a dozen plates and bring home a dozen negatives.

Mr. COLLIS exhibited some interiors of the Crystal Palace, by Messrs. Negretti and Zambra, sent by Mr. Ross as the work of his No. 2 triple lens. Mr. Collis was unable to state precise particulars as to equivalent focus or aperture used. This gave rise to a conversation in which the chairman expressed an earnest hope that makers would in future be induced to speak of the true equivalent foci of their lenses, and of the apertures by definite measure instead of by numbers which explained nothing.

Mr. GREENWOOD asked if Messrs. Negretti and Zambra were photographers. He believed not; and he thought it only fair, therefore, on the principle of honour to whom honour is due, that the artist's name should have been mentioned.

Mr. SIMPSON said it was a very common circumstance, perhaps sometimes to be regretted, that the real producer of a thing was unknown, the employer alone appearing before the world as the producer. This was especially the case with the photographic operator; but the case before them was not an unusual one. Messrs. Negretti and Zambra had the sole right to photograph within the Crystal Palace, and doubtless these were by one of their operators, and in accordance with common custom the pictures appeared as their work.

Mr. GREENWOOD said that was the point of which he complained. He believed these were by a namesake of the gentleman (Mr. Collis) who exhibited them. He thought that the system pursued by the Stereoscopic Company to Mr. England, of publishing his name with his productions should be more fully carried out.

Mr. COLLIS thought it was the general custom which could not well be avoided, that an employer should obtain the credit of what was produced by those in his service.

The CHAIRMAN said there was no motion before them, and he did not think it would be prudent for them as a society to pass any resolution on such a subject.

* Since the meeting, Mr. King has favoured us with a sight of one of these, a negative developed five weeks after exposure, which, with the exception of slight under-exposure, is clean and satisfactory. From Mr. Seeley's description of very short exposures, it appears probable that they may, in some measure, account for the results attributed to imperfect keeping.—Ed.

Mr. SIMPSON said he thought it would scarcely be necessary. He felt convinced that employers might without any derogation frequently allow their operators to share the credit of production, and a hint from the society deriving its force rather from the acclamation with which the remarks on the subject had been received, than from a formal resolution, would doubtless have the desired effect.

Mr. HART exhibited some specimens printed on different baths, one on a 70-grain nitrate bath, one on a 20-grain nitrate bath, and one on a 20-grain nitrate bath with 50 grains of nitrate of soda. There was very little perceptible difference in the results. By daylight, that with the nitrate of soda was blackest in tone, that with 70 grains of nitrate most purple in tone, and that with 20 grains of nitrate of silver only the brownest. There was little difference in depth or intensity; but the 70-grain bath gave the greatest sensitiveness.

Mr. HOWE exhibited a series of fine photographic transparencies of various kinds, by the aid of the magic lantern and oxyhydrogen light, which were much admired.

Mr. J. COLLIS was elected a member, and the proceedings terminated.

Correspondence.

TRANSFERRING NEGATIVES TO GUTTA-PERCHA.

DEAR SIR,—I have seen several letters in the NEWS lately on the subject of Gutta-Percha Transfers, and am surprised that the process is not more generally adopted. There is no difficulty in the operation, but what a careful manipulator would easily overcome, and the only objection is the smell of the benzole during the operation of coating the negative or positive on the glass, as this must be done in a room where there is a fire, it being necessary to set the gutta-percha by heat, otherwise it will dry opaque. In the first volume of the NEWS, page 203, I gave a very simple method of transferring collodion films to paper. The gutta-percha solution should be made with the very thin pink gutta-percha, torn into strips, and put into a bottle; the bottle should be more than filled with the gutta-percha, and the benzole poured on to it. It should then be placed near a fire with the cork loose. When all the gutta-percha is dissolved, and the liquid cool, the cork should be tightly fitted and the bottle put away till the solution is clear, when it should be poured into another bottle bearing the sediment. If left for some time, it will become a perfectly white mass, but is easily dissolved by placing the bottle in hot water. I find negatives print quite as well as when on the glass, and the film can be kept in a book between blotting paper with perfect safety. I have numbers that have been kept for years. Now that transparent stereoscopic slides are mounted with ground glass it would be a great saving in weight, risk of breakage, and expense, if the films were taken off the glass and put on to paper, and then mounted on a skeleton mount to keep them rigid. Gummed or gelatinized paper might be sold for the purpose. There is no fear of the film not coming clean off the glass, if the gutta-percha solution be thick enough and the glass placed in water for a minute or two.—I remain, dear sir, yours very truly,

THOMAS BARRETT.

Mead Vale, Red Hill, 19th November, 1863.

QUI CAPIT, ILLE FACIT.

DAR SIR,—In reply to a letter, signed B. L. Phillips, I claim the privilege of saying—

That, as I never saw, knowingly, backgrounds produced by this writer, I could have had no intention of injuring his, or, indeed, any other person's business; that when I use the word portraitists, I mean neither this, nor that, nor the other, but simply portraitists, and that when Mr. Phillips fails to understand what he reads, it is just possible that it may be due to something besides a want in the writer.

I have the audacity to differ from this person on more points than that of colour *versus* neutral tints in photo-

graphic background. For instance, I do not believe that a week's practice with the camera teaches you pictorial, perspective, and chiaroscuro; and I certainly *do* believe that in a photographic journal it is as legitimate to advocate the artistic as the scientific aspects of the *art-science* represented.

If the mere mention of a rival tradesman, unassociated with either praise or blame, so rouses the indignation of Mr. Phillips, what will his rivals say when they find him so modestly asserting that his own method of painting in "colours or tints" gives such very superior and "charming effects," and that his own productions prove it? Fie!

In conclusion, allow me most distinctly to state that I am *not* "a disappointed rival; and that the remainder of Mr. Phillips' letter being *contra bonos mores*, I have nothing to say thereto.—I am, dear sir, yours truly,

R. A. S.

PHOTOGRAPHIC LENSES AND DISTORTION.

SIR,—The modern photographic lens is a great triumph of optical art and science; and though it cannot yet be considered as having arrived at perfection, it reflects the highest credit on the skill of those who have bestowed so much pains and talent in satisfying the many requirements that the wants of photography have necessitated. As these lenses have had so much to do to please all parties, it seems hard to attribute to them defects to which they are not liable; and, with your permission, I will say a few words in their defence. They are charged with distortion. Now, I at once admit this defect so far as to acknowledge that, in the marginal parts of the field of view, lenses have this defect more or less according to their quality. Let this be termed *angular distortion*, and I admit its existence, inasmuch as the angles subtended at the eye by different portions of the object, are not, throughout the whole of the field of view, proportional to the angles subtended at the eye by corresponding portions of the image formed by the lens upon the focussing-glass, and, therefore, of the photographic picture formed by its means. This angular distortion does not exist, in the case of a good lens, in the central portion of the picture, but is generally palpable in its marginal parts; for example, when an animal is taken as large as the lens will admit, its extremities, if allowed to occupy the margin of the picture, will be out of proportion to the parts in actual situation.

But it is also said that a lens distorts those objects which are not situated in the same plane, perpendicular to the axis of the instrument; for instance, in taking a portrait, the hand is placed too far in front of the body, or if the foot be advanced again beyond this, and, as a natural consequence, the hand appears in the picture too large for the body, and the foot still more out of proportion, this apparent disproportion is said to be due to the imperfection of the lens in magnifying the nearer objects, and thereby distorting the picture.

This, however, is not a true explanation of the fact, that nearer objects do appear out of proportion to those more remote. The lens would act very imperfectly if it did not exhibit the nearer hand larger, *i. e.*, subtending a larger angle at the eye than the other, for this is the case with the eye itself. The nearer hand subtends at the eye a larger angle than that more remote and larger in exactly the same proportion as is apparent in the picture drawn by the lens placed at the same distance from the object. In the case just supposed, the hand would occupy the centre of the picture, or nearly so, and therefore there would be no angular distortion. To explain the apparent disproportion, the foot would be further from the centre, and therefore might be in some degree affected by angular distortion, which would make it appear in the pictures larger than would be due to its mere linear distance from the lens. In a picture, every object is mechanically drawn by a lens in the same proportion as its image, which is formed on the retina of the eye, the lens of the eye portray-

ing nearer objects on the retina magnified, so to speak, in the same proportion as those objects are represented on the focussing screen of the camera, allowing for angular distortion, if any, with which I am not now concerned, and which is owing to the picture being formed on a plane instead of a spherical surface, and also to the axes of oblique eccentric rays or pencils of light emerging from the lens or combination of lenses in directions not parallel to those of the incident rays, but diverging outwards. In the case of pencils of light emanating from objects at different linear distances from the lens, it is assumed that when diverging on to the lens from the same axis, they will emerge from it, and converge to force on the same axis, whether parallel or not, an assumption which, whether accurately true or not, is sufficiently so for the correctness of my reasoning.

Admitting then the fact of this apparent distortion, what is the explanation? Several considerations concur in this, but the principal one is that the picture is drawn upon a plain surface, and has not the relief necessary to convey to the eye that impression of difference of distance of the various objects which in vision is taken into account by the wonderful and mysterious organ of sight. In other words, the picture has not a stereoscopic affect.

A gentleman who lately gave a lecture upon Photography, among other recommendations, some pertinent and some the reverse, advised that in portraiture the features should be in the same place, perpendicular to the axis of the lens, lest this distorting trick of this reduced instrument should exhibit the suffering subject with a swelled chin or a hyper-intellectual forehead, not apparently being aware that the lens would represent the features, however placed, in the same proportion as they are subtended at the eye, and that the proper remedy in such cases would be an infusion into the picture of such an amount of light and shade as would secure as far as possible the relief requisite to obviate this inartistic distortion.

The naked outline of objects, *e.g.*, boxes, or chairs, drawn in exact perspective appear out of proportion until they are clothed with light and shade, and invested with the appearance of solidity; and it is to his skill in giving proper relief to his figures, as well as in the avoidance of all excess in attitude, that the artist must look for the concealment of this apparent distortion, and not to improvement in his lens which is indeed quite guiltless in the matter.—Yours truly
M. A.

IN SELF-DEFENCE.

SIR,—The seemingly angry reply addressed by Mr. Phillips against "R. A. S." (whose inoffensive remarks on backgrounds I thoroughly endorse, as being *very* similar to those I have myself made), contains an ungenerous statement, calculated, if not intended, to damage an important branch of my business.

The cloths I paint for the floor in connection with backgrounds, do not, by being attached to the latter, render a fresh cloth necessary for every background, as Mr. Phillips asserts, except when backgrounds of an entirely different character are made use of.

Possessing an intense horror of squabbles arising out of trade jealousies, I only ask you to insert this simple statement as something due to those who are dependent upon my business for their support.—Yours truly,
A. H. WALL.

6, Dartmouth Park Road, N. W., Nov. 23rd, 1863.

PHOTOGRAPHY IN COLOURS.

SIR,—Having read with great interest what you occasionally published with regard to photography in colours, and many times thought about the chances we have to see the art brought to that desired pitch of perfection, the article from *Galvani* makes me wish to say something about the subject.

The invention of those two gentlemen in Italy does certainly not look like a step in advance, as they only substitute painting certain parts of the picture over with chloride of gold to painting them over with colours, and I am afraid the latter process is decidedly the better one.

In my opinion the problem of photography in colours is, for the present, to be solved by the chemist, not by the photographer; for, to do the work, there is wanted neither more nor less than a chemical which, by a tolerably short exposure, turns white in white light, black in the dark, green in green, yellow in yellow light, &c., and the colours of which can be easily and instantaneously fixed.

Whether such a chemical exists among the infinite number of chemical compounds that occur or may be produced in the animal, vegetable, and mineral kingdoms, is a question to which we may almost confidently answer, no.

It is true we see, for instance, on the surface of plants and leaves, a chemical which turns *green* in *white* light, but even if we were able by analysis exactly to determine the compound, and produce it, there would be nothing gained. The beautiful green colour soon disappears when the organism of the plant no longer supplies fresh matter; and besides, the circumstance that it turns green in white light would make it useless.

Still, people who like to make experiments, spend skill, money, and time, in searching after the wished for art of photographing in colours, may not, after all, find all their endeavours wasted; but, like the alchemists of old, make many valuable discoveries in searching after something that is unattainable.—I remain, sir, yours truly,

AUGUST BUSCH.

Photographic Notes and Queries.

STORMY WEATHER AND PHOTOGRAPHY.

DEAR SIR,—We have just passed through a succession of terrific gales; those gales affect photographers in other ways than that of smashing their glass cases, and stopping work, &c., more especially those who live near the coast, and possibly for many miles inland. The air in those hurricanes is saturated with saline particles, as any one by tasting the glass on the outside of his window can testify; and after the rain which almost invariably follows a cessation of the storm, this salt is carried by it into tanks and other reservoirs, rendering it almost unfit for washing purposes, and operating most disastrously in the first washing of prints, converting the nitrate of silver into such irregular patches, as no after-washing can eradicate. No doubt most photographers are perfectly aware of this, and use distilled water in their first washings; if not, the refreshing of our memories can be of no harm.—Truly yours,

CORNISH CHOUGH.

Talk in the Studio.

CARD ALMANAC FOR 1864.—Mr. H. B. Pritchard has designed and photographed a very clever card almanac for the coming year which will form an interesting and useful addition to photographic albums. The centre of the card is occupied by the almanac, which is arranged in a very simple tabular form. Around it, grouped with considerable taste and skill, are the title pages of about half a hundred periodicals, comprising the chief representatives of the daily, weekly, and monthly press. Photography takes a prominent place, and is represented on the card by the PHOTOGRAPHIC NEWS. The card is as perfectly photographed as it is well designed, and will, we doubt not, have the large circulation it deserves.

OBITUARY.—Mr. Fitz, of New York, one of the earliest American photographers, and one of the ablest opticians of the States, died on the 31st. ult., after a brief illness. Our readers will remember allusions in the letter of our American Correspondent to an improved Globe lens he had recently constructed.

THE ALLEGED EARLY PHOTOGRAPHS.—The history of the supposed pre-Daguerreotype photographs has excited considerable attention from the general public, and good articles on the

subject have appeared in the *Saturday Review*, the *Illustrated News* and other papers. Great stress appears to be laid by the writers in the general press on the fact that the paper pictures contain no trace of silver, as though that were a remarkable fact in connection with photography. A correspondent of the *Glasgow Herald* noticing this, calls attention to Mr. Mercer's pictures, obtained with the salts of iron, which he thinks are almost unknown to photographers. Mr. Mercer has perhaps scarcely given his experiments the publicity to which they are entitled, but well-informed photographers are familiar with his labours. The absence of salts of silver is of course no argument in the subject of photography, as, besides the various iron processes, there are those in which carbon has been largely used, and also the salts of uranium, &c.

MATTHEW BOULTON'S CAMERA.—We have received from Mr. Kirkby a description of the missing camera referred to by Mr. Smith in his history of the early photographs. Our correspondent saw the camera some years ago in the hands of Mr. Powell, and gives us a detailed description and drawing of it, which will appear in our next.

To Correspondents.

- I. M. L.**—Side light is very important in taking card pictures; nevertheless, with a top light in the position of No. 2, and fifteen feet wide, it would be possible, with skilful arrangement, to get good results. We prefer the design of No. 2, but would like some side light as well. See article on "Card Pictures" in our last.
- G. P. H.**—The paper to which you refer owes its offensive smell to some peculiarity in the preparation. You cannot do anything to alter it that we know of. It gives good results we believe, but is certainly unpleasant to use. 2. It is not necessary to use distilled water for the hypo bath. The time of immersion with the strength you use, one part in five, should, with thin soft paper, be about 10 minutes; with stout hard paper, twice that time. 3. Prints may be properly toned in any time, from 5 minutes to an hour, depending on the strength of the gold bath and other conditions.
- CAMERA.**—We should place the optician's name in much the same order as you have done, 1, 2, 3.
- T. C.**—It is contemplated by the Photographic Society to open an exhibition early in the coming year; but when or where is uncertain, as a suitable place has not yet been found. 2. The purple tint in a toning bath is due to the reduction of metallic gold in a very finely subdivided form, probably produced by the heat you apply. 3. It is impossible to state how much sulphide of potassium will be required to precipitate the silver from a given quantity of hypo solution, inasmuch as it is impossible to state how much silver is present. You can only ascertain by testing. Take a portion of the supernatant liquid in a test tube or small phial, and add a little solution of sulphide of potassium to it; if a precipitate fall, there is still silver; if not, take another portion, and add a little nitrate of silver to it; if a precipitate fall, it indicates excess of the sulphide solution. 4. Your chloride may become dirty and discoloured from many causes. Wash it well to remove all impurities.
- A. W. B.**—Amongst the makers your name, decidedly No. 2 in our opinion. 2. It is not necessary to remove the stopper from the bottle previous to sunning the bath.
- EXPOSURE.**—It is a little uncertain to what lens Dr. Kemp refers in the passage you mention. In another place he refers by name to Dallmeyer's new stereo lens (double); but here it seems probable that he refers to an ordinary single stereo lens of 5 or 6 inches focus.
- PHOTO ENGRAVER.**—The cause of the defects in your negatives, both stains and cracks, appears to be imperfect washing after fixing. The fixing salt, probably hypo, has remained largely in the film, subsequently crystallizing out, and causing spots, stains, and cracks. They have the effect of too much top light, and are not sharp. The lens does not seem suitable for card pictures standing figures. 2. The No. 1 B is not so rapid, nor does it cover so well as No. 2 B, but is an excellent lens; it will, under ordinary circumstances, cover a 5 by 4 plate. It answers very well for copying. We cannot state any precise time of exposure, as that must vary with circumstances. 3. So far as our experience goes, collodion No. 4, in your list. 4. The only mode available of securing portraits at night is by the aid of Moule's Photogen. 5. A side light is desirable, but a top light, managed as we described in the first article last week, will do. A west side light will present no difficulty except in the afternoon, and then must be stopped out with blinds.
- J. GILBERT.**—The last edition of "Hardwich's Manual" is, we understand, out of print. There is a rumour of a new edition in course of preparation, but we have seen no authoritative announcement. If we meet with a copy we will let you know. 2. We cannot tell you the name of the largest manufacturer of protosulphate of iron. We believe there is a very large manufactory at Walker, near Newcastle-on-Tyne.
- FELIX.**—We never met with a faded Daguerreotype. If exposed to the atmosphere or impure gases, the surface becomes tarnished, and the picture almost invisible. To remedy this make, a moderately strong solution of cyanide of potassium—say 30 grains to the ounce. Wet the surface of the Daguerreotype first with water, holding it under a tap until the water flows all over without greasy marks. Then pour on the cyanide solution, which will quickly remove the tarnish. Watch carefully, so as to stop the action before the image is attacked; rinse well, finally, with distilled water, and dry, by applying the flame of a spirit lamp to the back of the plate, and blowing gently at the surface.
- F. VINCENT.**—The use of gelatine or gum tragacanth will aid in giving vigour to your developed prints—the exact proportions must be matter for experiment. The solution, which must also contain the salting preparation, may be brushed on or floated. Increasing the proportion of chloride, and decreasing the proportion of bromide, will also tend to increased brilliancy.

P. C. J.—The kind of fog to which you refer, as appearing to exist between the film and the glass, may arise from several causes. Dirty glasses are the most common cause, and some samples of glass will cause it, no matter how carefully cleaned they may be. Cold and damp weather tend to produce it, when other causes are there. Under-exposure, and forcing the development, will produce, if the slightest tendency exist in the glass. A thin-bodied collodion materially aids in producing it. When you see the tendency, use a thick-bodied collodion, well cleaned, good glasses quite dry when coated, full exposure, and plenty of acetic acid in the developer. A few drops of tincture of iodine to each ounce of collodion is often an advantage in such cases.

J. MOONEY.—See our advertisement columns. We cannot recommend any especial house. Prices will be easily obtained from any house.

TANTRIS PLATES, Bristol.—We cannot make out the signature of this correspondent. The best picture is No. 3; with a little more brilliancy it would have been a good picture. Nos. 1 and 4 are very unsatisfactorily lighted, there is possibly from the cause you name; they look very like the result of an uneven film of collodion. We have seen them, however, when the film was perfectly even, and are uncertain of their cause. With care in choosing your time when your subjects were well lighted, you would get better pictures with the same plates. 2. Mr. Williams uses a silver bath containing from 30 to 50 grains with a weakly salted paper; 80 grains with ordinary commercial papers. The ordinary acetate bath, containing 30 grains of acetate of soda to 1 grain of chloride of gold. Immerse in fixing bath for 15 minutes.

A LADY MEMBER.—We shall have something more to say on the Exchange Club in a week or two. We could scarcely undertake the invidious duty of deciding the classification of prints for exchange, as no one would be satisfied. The dissatisfaction of many members with the position assigned to their prints by the referees has been one of the difficulties of the late system. We shall have pleasure in assisting you by such classification; but we should hesitate to undertake that duty generally. 2. The dull surface to which you refer is probably caused by using water, which forms insoluble salts of silver apparent chiefly on the edge to which the drawings run. The use of distilled water would, in such case, be a remedy. We are quite uncertain what collodion suitable for the purpose you can obtain in Glasgow. When the prepared albumen shows signs of decomposition it is not safe to use it.

THOMAS DAVIES.—You are under no necessity of registering your pictures, or sending them to Stationers' Hall or elsewhere. Registration is a privilege to protect you from piracy, as, without registration, you cannot prevent your pictures being copied. Registration will not prevent another person from taking another view of the same subject, only from copying yours. It must be a negative from one of your prints to be a piracy. 2. The extent to which you may use water is a matter entirely governed by the arrangements of the water company, and may vary with each one. Additional charge is generally made for water to photographers. 3. We should prefer to have the north light as a side light.

A. A.—The only formula we can give you for copying oil paintings is the general advice to use a freely bromized collodion, and give plenty of exposure. Also avoid a light which causes the "handing," or impasting, of the painting to cast numerous small shadows.

J. H. S.—Either of the lenses you name are good; but, if you can conveniently afford it, by all means have No. 2. It is worth all the difference in rapidity, depth, and definition.

ONE ANXIOUS TO LEARN.—Your diagram is not very clear, but if we understand you aright, your sitter cannot receive much north light, if a building projecting above your glass room is placed at six yards distance to the north. If the east end be quite open and unobstructed, place your back-ground to the south, so that the side light reaches your sitter from the east.

PETER GRIFFITHS.—The only secret lies in having the prints well rolled, then lighting properly. Diffused light answers best; any direct light will make the surface cast shadows and show its texture. The diffused light of a room is best.

E. C. L.—Your request for "information on the electric" light is somewhat indefinite. There is no specific work on the subject, but a great deal of information has appeared in our pages from time to time, as to its application to photographic purposes.

A. H.—Your name will be duly proposed.

AUGUST BESCH.—The weather has been very unsuitable for trying collodion. From a trial we did make we think the collodion very excellent. We received Mr. Lobb's charming picture and noticed it, but he did not mention your name. Its excellence indicated that all the chemicals employed were good, in good condition, and skilfully used.

M. A.—The note to your letter was probably just; but was better suppressed. We prefer to avoid giving pain, without it is necessary to secure some good end.

J. FOOTE, ALPHA, A. S. WATSON, E. S., W. RUTHERFORD, FRANK W. GOOD, and J. SHERRER.—Received, and shall have attention.

W. NOTMAN.—The box received, and the enclosures forwarded. Notice shortly.

C. W.—To what extent you are bound by the agreement we cannot tell you. That is a question for a lawyer. As to the payment of your fare, common sense dictates he should hand you the amount, and not, by purchasing a ticket, compel you to go by a certain train.

R. HUNT.—We are requested to inform this correspondent that the charge for insertion 13 times would be 120 francs. Several Correspondents in our next.

Several important articles in type are compelled to stand over.

THE TANNIN PROCESS; IS IT SLOW OR RAPID?

VERY considerable difference of opinion seems to exist as to the degree of sensitiveness possessed by tannin plates and the amount of exposure they require. Mr. King's exposures, described in our last, are regarded by many as excessively slow. As discrepancies of experience on such subject often depend on minor points of manipulation, we here give the details of practice of two gentlemen who have obtained good results with comparatively short exposures.

THE TANNIN PROCESS.—SHORT EXPOSURES.

BY H. C. JENNINGS, JUN.

As an admirer of Major Russell's beautiful tannin process, I was somewhat surprised to hear of the long exposures given by Mr. King. I work rather large plates, $\frac{1}{2}$ size nearly, lens No. 1 triple, quarter-inch stop; for a brick building with dark foreground, I gave three minutes on Friday, November 13th, at 8 o'clock in the morning, day rather dull. Certainly my lens is shorter focus.* But still I do not think that it accounts for the vast difference in the exposure Mr. King has been giving and mine.

My method is not new; I have chiefly obtained it from the PHOTOGRAPHIC NEWS, yet it may be of interest to some of your numerous readers:—

1st. Clean plates very thoroughly and coat them with any good collodion working well with iron development (I prefer Rouch's bromo-cadmium collodion) sensitized in the same bath as for wet negatives for about three minutes, drain the plate well, and,

2nd. Place in a dish of distilled water and rock about for half a minute, proceed with another plate, and,

3rd. Wash thoroughly under the tap, swirl the face with distilled water, drain slightly, and,

4th. Coat twice with

Tannin, pure	5 grains.
Distilled water	1 oz.

Pour off into an empty bottle and place the plate on a levelling stand, and pour on gently enough tannin solution to cover the face; let it remain on whilst another plate is being washed. When the second plate is ready, pour off the tannin from the first (it may be used over again), let drain, and place to dry in any convenient place free from dust.

To develop, varnish the edges with lac varnish, moisten the film under the tap, and pour on the surface a 10 grain solution of pyro in distilled water. Let the detail come well out, then pour off the pyro solution into a glass, and add one, two, or three drops of the following silver solution, according to the size of plate:—

Silver	10 grains
Citric acid	20 grains
Water distilled	1 oz.

Let it intensify as much as possible; if over-exposed, add more silver, but cautiously, or the negative will be apt to give an abominable "soot and whitewash" print. If there is reason to believe the picture under-done, use the pyro without silver, rather warm, and it will in most cases make up for the deficiency in the exposure.

But no true photographer will tolerate *under-exposure*. It is far better to give at once the full exposure than to risk getting foggy or stained negatives by after doctoring. I generally fix with cyanide; but hypo might perhaps preserve the density better. Enclosed is the print of the house mentioned in the first part of my letter. It is by no means perfect, but is sufficient to prove what can be done with a little perseverance in this beautiful and simple process.

In conclusion, I may state that I use the tannin solution used for the first two coatings over again, adding a grain or so tannin to each ounce.

[The print enclosed by our correspondent is amply exposed, clean, and full of detail.—Ed.]

NOTES ON THE TANNIN PROCESS.

BY G. W. O.

LIVING on the outskirts of Dartmoor, and no brother amateur—I believe no professional photographer residing within at least twelve miles of this village—I have to work out by myself the causes of my successes and failures. The arrival, therefore, of your paper is always looked forward to with interest on a Saturday morning; to it I am much indebted for valuable information, and in hopes of adding a mite to aid workers in the tannin process, I send the way in which I proceed. During this past year I have not lost a view from a faulty dry plate; the few failures that I have had were caused by trying to take such views as "a flood during a storm of hail or rain," when the failure has been from a want of light. I have not tried any of the quick dry processes, as the keeping qualities of the plate seem to be in an "inverse ratio" to the rapidity. My dry plates, during the early part of the year, were exposed five minutes (this was the time through the whole of July); the last I took was on 26th of October, and was exposed fifteen minutes. All of these were rather over-exposed; they were developed without any addition, on account of under-exposure. For stereoscopic plates I use a pair of Ross's lenses, for half-plates one of Grubb's. All my chemicals (except hypo and tannin) are from Ponting, at Bristol, so that they can be relied upon. As many of my views on and about the Moor require long walks, I do not like to run the chance of the film washing off, and therefore always coat with gelatine. The trouble is little, and regret at the disappearance of a view that has cost some hours' walking to obtain, is great. To the gelatine I now add the iodide and bromide of cadmium, as Major Russell advises, and my negatives are now nearly as transparent, and print as quickly, as my iron negatives. To save the trouble of referring to the work, I put the quantities at

* The triple of 8 inches focus, $\frac{1}{2}$ inch stop, and the applanatic of 12 inches focus, $\frac{1}{4}$ inch stop, have nearly equal relation between aperture and focus.

foot. The collodion that I use is Ponting's iodized; this I keep for several months, and mix with it, in a separate bottle, the bottoms from the bromo-iodized that I use for the instantaneous work, so that no collodion is wasted. After removing the plate from a 30-grain nitrate bath, made according to directions on the bottles of Ponting's iodized collodion, I place it in a flat dish nearly filled with rain water, and having passed the hook of a little stick under it, keep lifting the plate up and down gently until all the greasy marks have disappeared. I then leave the plate, pour the collodion on another glass, and place it in the nitrate bath, and then I return to the plate left in the rain water. This I again move about with the hook to see if any lines exist, and if they do not, I transfer it to dish "No. 2," also filled with rain water, where I again move it about for a minute, then, by the hook, draw the end of the glass over the edge of the dish, and (having blotting-paper between the first finger and thumb of my left hand and the glass) lift it by the corners on to the pneumatic holder. Having let the water drain for a few seconds, I pour on the tannin so as to run in a gentle stream into the same beaker from the end near myself to the corner from which the collodion drained. I pour the next tannin on four times from beaker "No. 1," which carries away any water, and then the same number of times from "No. 2." (As the tannin in "No. 1" gets wasted I add from "No. 2," always putting the fresh mixture in "No. 2.") Having let the super-abundant tannin run off, I leave the plate to dry in a box kept on purpose, and then return to the plate in the bath (about five minutes having elapsed since it was put in), and proceed in the same manner. I put fresh water in the first dish after every fourth, and in the second after every sixth plate.

The preservative solution that I use is in the proportion:—

Tannic acid	15 grains
Distilled water	1 ounce
Methylated spirit	$\frac{1}{2}$ drachm

The developers, pyrogallie acid, nitrate of silver, and citric acid, as recommended by Major Russell in his first edition, keeping one stock bottle of the pyrogallie acid and alcohol, and another of nitrate of silver, 20 grains to the ounce. At foot I put the quantities of these developers.

The plates prepared as above I have kept more than six months, and they were apparently quite as good then as when freshly made. Not wishing to waste plates, I have not tried the shortest time of exposure that they would require, but I think that instead of five minutes, as before mentioned, a good picture might be got in three and a half or four, but as the over-exposure is easily remedied in the developing, and as I put on gelatine to save the trouble of doing the work again, for the same reason I prefer a little over-exposure to a weak or ruined plate. I develop as soon as possible, but have kept the negative a week, and it was then quite sharp and bright. Mr. King's process, as described in his paper printed in the PHOTOGRAPHIC NEWS of 27th November, differs for the most part from mine in manipulation, with two exceptions, *i. e.*, he does not use a gelatine coating, which I do; and he uses new bromo-cadmium iodized collodion, and I use old, simply iodized collodion, for the quantity of bromo-iodized from the bottoms of bottles is but trifling. With respect to the washing, we both agree as to the moving, but do it in different ways, and I think that mine is the least troublesome. We both use the same proportions of tannin, but Mr. King does not use the same portion twice, which I do. In developing, I lay the plate in a dish of common pump water, and let it stay there for four or five minutes; there is no danger of the gelatinized film coming off, or swelling, or cracking, it will bear a deal of rough usage. The levelling stand I never use. In developing, we use the same chemicals, but rather differently. If there are signs of over-exposure (which show themselves directly the developer is poured on) I pour back

the developer into the beaker, and add a few drops of the nitrate of silver and citric acid mixture which corrects the evil. If there are signs of under-exposure, I pour back and add some more drops of the pyrogallie.

Like Mr. King, I do not "hope to communicate any novelty," and a person conversant with Hardwich and Major Russell's works will find much of the above therein. A photographer who has succeeded in one way of working had better persevere in that, although another may appear easier; but to beginners who have not settled into one plan of working, practical suggestions are of the greatest use; following, therefore, Mr. King's good example, I send you the above notes of my way of proceeding, hoping that they may be acceptable.

Gelatine Solution.

Nelson's gelatine	40 grains
Glacial acetic acid	40 minims
Distilled water	8 ounces
Iodide of cadmium	3 grains
Bromide of cadmium	3 "
Small piece of iodine				

The three last to be dissolved first in a few drops of water, and then added—

Developers.

No. 1. Pyrogallie acid	72 grains
Alcohol (absolute)	1 ounce.
No. 2. Nitrate of silver	20 grains
Citric acid	20 "
This quantity reduced in cold weather.				
Distilled water	1 ounce.

For use, diluted No. 1.

No. 1. Developer	10 minims
Distilled water	1 ounce.

For developing a stereoscopic plate, to 3 drachms of diluted No. 1, add from 10 to 20 minims of developer No. 2.

[It will be seen that the exposures of G. W. O. are longer than those of Mr. Jennings; whether this be due to the latter using more bromide, or to the difference in the lenses, we cannot say.—Ed.]

ON IODIDE OF SILVER AS A SENSITIZING AGENT, AND ESPECIALLY OF THE ACTION OF TANNIN, AND SOME OF THE OXIDIZABLE SUBSTANCES, IN PHOTOGRAPHY.

BY A. PORTEVIN.

THE action of light upon iodide of silver is of three kinds, according to the condition of that body and of the substances it is associated with.

1st. It is *nil* upon chemically pure iodide, isolated from every substance which retains the iodine light tends to separate.

2nd. It modifies the iodide when metallic silver, nitrate of silver, and other soluble salts of this metal are present, and imparts to it the property of exciting the reduction of the acidulated solutions of silver by known developers, sulphate of protoxide of iron, gallic or pyrogallie acid, and also by mercurial vapours; and it is this action that is turned to account to obtain negatives in the camera.

3rd. It brings the iodide to the state of inert iodide under the action of the developers, or when acted upon by light, it is covered with a solution of alkaline iodide. This action is the same with regard to metallic silver, which induces the belief that sensitized iodide of silver is brought partially to the metallic state when it has lost a certain portion of iodine to form a sub-iodide. These well known facts apply to the other insoluble compounds of silver, and particularly to the chloride, bromide, &c.

Starting from this point, and wishing to explain the part played by the principal bodies which, up to the present

time, have been associated with iodide of silver upon the sensitive film, I first prepared a film of inert iodide, that is to say, rendered inert by an excess of alkaline iodide and exposure to light; then I carefully washed it. In this state the iodide of silver is wholly unacted upon by the developing solutions, even after a long exposure, but if the smallest quantity of a soluble salt of silver be added—the nitrate, for example—it becomes sensitive and proper to receive a latent image in the camera. I had no occasion to verify this fact, it is familiar to every photographer, but I submitted to experiment acetic acid, the gums, albumen, gelatine, sugar, honey, solutions of resins in alcohol, spirits of turpentine, and certain bodies, such as salicine, alloxantine, &c. None of the substances rendered iodide of silver sensitive to light. But it was not so when I employed tannin, suggested by Major Russell: this body communicates to insensible iodide of silver, that is to say, completely free from nitrate of silver, a sensibility at least equal to that obtained from nitrate of silver itself. Tannin is therefore a *sensitizer*, and it must be regarded as such and not as a *preserver*, as all the substances are termed which are employed to preserve the sensibility of plates, or rather to prevent them from fogging completely in presence of developers in developing the negative picture.

We might have anticipated this property in tannin, since in the method that succeeds the best for preparing dry collodion for the tannin process, we entirely obliterate the nitrate of silver which covers the plates, by the final washing in water, recommended by the author of the process; in fact, this water containing alkaline carbonates and chlorides renders insoluble the last traces of free nitrate of silver on the surface of the plate; it is, moreover, by remarking this fact that I have been led to make the present task.

I thought that other very oxidizable bodies might possess the same properties as tannin, but I have experimented only with those I had at hand, and recognized that the solutions of sulphate of protoxide of iron, gallic and pyrogallie acids act like tannin. We shall, I am certain, discover others, which, alone or mixed, will prove more powerful sensitizers, perhaps, than the soluble salts of silver or tannin, which are the only ones employed hitherto. Perhaps new sensitizers will permit them to replace iodide of silver by other insoluble salts of this metal, and every thing leads to the belief that already bromide of silver employed alone, appears, under the influence of tannin, to be more sensitive than the iodide, at least, according to the statement of Major Russell.

I have wished to turn to practical account this purely theoretical but well-established fact—the sensibility communicated by tannin to iodide of silver—to avoid, if possible, all the causes of failure met with in the production of negatives, such as spots, fogging, insensible films, &c.—accidents which usually proceed from other reactions than that of light upon the sensitive iodide of silver, for they are due to the impurity of the materials, which give to the iodide of silver the property of exciting the reduction of the developing solutions. This modification takes place at the moment of the preparation of the sensitive film of iodide; or, rather, during the time, more or less long, which elapses between its preparation and exposure in the camera, and mostly during the development of the latent picture.

The method I propose is applicable to all known processes, whether we operate with waxed paper, albumen, gelatine, or wet collodion or dry: moreover, the actual and special purity of the materials, paper, collodion, and nitrate baths, will not be absolutely indispensable. This method has, it is true, been pointed out and adopted in part, but not from the same point of view—that is to say, the complete suppression of nitrate of silver as the final sensitizer of the iodide of silver.

The following is my method, in which I shall speak only of the employment of iodized collodion, having employed no other. I prepare this collodion in the usual way, adding $1\frac{1}{2}$ per cent. of iodide to it—coating a plate, and sensitizing it in a nitrate of silver of bath, strength 8 to 10 per cent.

For example, I wash the coating of iodide of silver, formed in order to remove the greater portion of the nitrate covering it; and what will probably surprise many operators is, that it is not necessary to perform this operation in the dark room.

The plate being freely washed, I cover it with a solution of iodide of potassium (about 4 of iodide to 100 of water), this solution being previously saturated with iodide of silver by the addition of a few drops of the solution of nitrate to the bottle containing it: moreover, this solution of iodide of potassium will serve until exhausted; and it is not necessary to make a bath, as it is sufficient to pour it again and again upon the film of iodide of silver and back into the bottle. I perform this operation in full daylight. And it is very essential to expose the surface thus treated to light for at least a few minutes. The object of this treatment is to destroy all germs of spots or fogging which come out during the final development.

I next wash the plate in plenty of water, to remove as much as possible the alkaline iodide, which has performed its task, and I then have a film of iodide of silver wholly insensible to light, and incapable of exciting the reduction of the developing solutions. To render the plate sensitive, it suffices to pour on its surface, in the dark room, the aqueous solution of tannin of 5 per cent. strength, it is then quite ready for exposure in the camera, and it is also as sensitive as a plate sensitized by nitrate of silver.

To cause the latent picture to appear, I wash the plate to remove the excess of tannin, then I pour upon the exposed surface a solution of aceto-nitrate of silver, of the strength of 2 or 3 per cent., and then the developer, sulphate of iron or pyrogallie acid. The development takes place precisely as in the usual methods, but what is no less remarkable than advantageous is, that we thus obtain with certainty, and without very great precautions, very clear negatives, vigorous and without spots.

Instead of employing immediately the film sensitized by tannin, it can be reserved for the dry process, as it will keep a much longer time than if the nitrate of silver remained on its surface. We can also prepare in advance plates with inert iodide of silver, leaving them to dry, and sensitizing them by the aqueous solution of tannin, or what in this case is preferable, its alcoholic solution; all these methods, I repeat, will give excellent results.

I give here one method only; all I can say is, that this method, which may be applied to all known processes, requires much less care, and particularly, chemicals less pure with respect to their special and chemical condition, than is required in the ordinary processes, in which nitrate of silver enters wholly, or in part only, into the sensibility of iodide of silver.—*Le Moniteur de la Photographie*.

PHOTOGRAPHIC CHEMICALS:

THEIR MANUFACTURE, ADULTERATION, AND ANALYSIS.

CADMIUM SALTS (*continued*).—By far the most valuable compounds which this metal forms are those with chlorine, bromine, and iodine. Chloride of cadmium is best formed from the metal itself. As metallic cadmium is of great use in preparing these valuable photographic chemicals, it will be found convenient to keep it in the granulated form. To obtain it thus, take some of the metal and melt it in a clay crucible, either at a gentle heat in a fire, or, preferably, over a gas furnace. In the latter case it will be found advisable to conduct a stream of coal gas into the upper part of the crucible by means of a glass tube, and place the cover loosely on. The gas which escapes at the edge may be ignited. The object of this is to protect the surface of the melted metal from contact with the atmosphere, which would oxidize it, causing waste. When thoroughly melted, have ready a tall jug full of distilled water, then seize the crucible tightly with a pair of tongs, and pour the melted metal in a thin stream from a height of about two feet, into the water. The cadmium will form a very bulky granulated

mass: it must be quickly drained on a cloth, dried by artificial heat, and preserved for future use in a dry, well-stoppered bottle.

To prepare the chloride, take a convenient quantity of this granulated metal, place it in a glass flask, and pour over it pure concentrated hydrochloric acid, diluted with its own bulk of water. Action commences immediately, and it may be continued by the aid of gentle heat. When the cadmium is perfectly dissolved, evaporate the solution, if necessary, and allow it to cool. Chloride of cadmium will separate in the form of hydrated rectangular four-sided prisms. These effloresce in dry air, and lose their water when heated, becoming converted into the anhydrous chloride. This compound readily fuses, and, after cooling, has the appearance of a transparent mass of a metallic pearly lustre, and lamellated texture. At about a red heat it volatilizes, and may be obtained by sublimation in transparent micaceous crystals. When the fused or sublimed salt is exposed to the air, it loses its transparency and lustre, and crumbles to a white powder. Chloride of cadmium contains 38.73 per cent. of chlorine, when in the anhydrous state; it is easily soluble in water, but only slightly so in alcohol and ether. It is, however, sufficiently soluble to communicate marked properties to iodized or iodo-bromized collodion.

Bromide of Cadmium, from its solubility in alcohol and ether is largely used in photography. When dry, cadmium is added to bromine, no apparent action takes place, as the film of bromide of cadmium first formed on the metal is insoluble in bromine, and protects the cadmium from further action of this liquid. If water be added so as to dissolve the bromide, as it is formed, the metal is rapidly attacked, and a solution of bromide of cadmium is the result. Upon evaporation and subsequent cooling, the salt separates in the form of white efflorescent needles having the composition of

When heated to the boiling point of water, two of these atoms of water go off, and the other two are expelled at a temperature of 200° C. The crystals assuming an enamel-like appearance, but not fusing. When suddenly heated, the hydrated crystals fuse in the water of crystallization, and are rapidly converted into the anhydrous bromide. This latter compound may be also formed by the action of vapour of bromine upon the metal, at a heat approaching redness. The bromide being volatile at this temperature, sublimes as soon as it is formed; and leaves a clean surface of metal to the further action of the bromine. The sublimed bromide of cadmium occurs in white rounded laminae, having a mother-of-pearl lustre. It dissolves without decomposition in hydrochloric and acetic acid, but is decomposed by hot nitric acid. Water, alcohol, and ether dissolve it readily. The anhydrous salt 58.34 per cent. of bromine.

Iodide of Cadmium is one of the easiest salts to prepare. Place some granulated cadmium at the bottom of a flask and cover it with water; now apply gentle heat, and add iodine. Rapid combination will take place between the two; the iodine will be quickly decolorized, and must be replaced by fresh quantities of the same element until all, or nearly all, the cadmium is dissolved. Towards the end of the operation, the iodide of cadmium may crystallize out: this had better be prevented by warming the liquid, or by adding more water. Filter the solution if necessary, evaporate, and allow it to cool. Unlike the bromide and chloride of cadmium, iodide of cadmium does not unite with water in the act of crystallizing. It fuses very easily, and when crystallized, either from the fused state or from an aqueous or alcoholic solution, it separates in large transparent and colourless six-sided tables, permanent in the air, and having a brilliant lustre resembling mother-of-pearl. The crystals dissolve readily in water, alcohol, or ether, and is deposited unchanged from these solvents on evaporation. Iodide of cadmium contains 69.23 per cent. of iodine.

The chloride, bromide, and iodide of cadmium, unite with ammoniacal salts, forming compounds which are not without interest. Chloride of cadmium dissolved in water and mixed

with an equal atom of chloride of ammonium yields, when concentrated, silvery needles containing one atom of water; these, however, gradually disappear, and are replaced by large anhydrous rhombohedrons, which are soluble in water, and slightly so in alcohol; their composition is Cd Cl , $\text{NH}_3 \text{Cl}$.

When ammonia is added to a solution of chloride of cadmium, a white precipitate is produced, which dissolves on the application of heat, and is deposited in the form of a crystalline powder in cooling. When dried and heated, one atom of ammonia goes off. The composition of the precipitate is NH_3 , Cd Cl .

When a strong solution of bromide of cadmium is saturated with ammonia, it yields, on evaporation, small crystals, which have a composition of NH_3 , Cd Br . When rapidly cooled, the compound separates in crystalline grains, and when slowly cooled, in regular octohedrons.

A similar compound is formed by the action of ammonia on iodide of cadmium; the composition being NH_3 , Cd I .

Chloride of cadmium dissolved in water and mixed with an equivalent quantity of chloride of potassium, unites with it to form a double salt, having the composition Cd Cl , KCl . It is slightly soluble in alcohol, more so in water.

A similar compound is formed when equal atoms of bromide of cadmium and bromide of potassium are dissolved in water and evaporated together. The double salt separates in the form of hydrated needles, very easily soluble in water and slightly soluble in alcohol.

When equal atoms of iodide of cadmium and iodide of potassium are dissolved in water and the solution evaporated, a double salt of the two is deposited. According to Crofts, this is not crystallizable, but is very easily soluble in water, and slightly so in alcohol. With soda salts cadmium forms similar compounds.

It is very probable that some of these double iodides, bromides, and chlorides, might be of considerable use in photography. At first it was considered that so long as photographers got the right amount of iodine or bromine in collodion, it did not matter what was the base with which the metalloid was accompanied; but later observations and experiments showed that this was not the case. It is true that the base has no direct action on the photographic properties of the sensitive silver salt, but it has a very strong indirect action by its power of modifying the collodion and pyroxyline. Almost every base has been found to have a peculiarity in this respect; and it is advisable, therefore, for experimentalists to press into service all the new compounds they can meet with, in the hope of obtaining some which possess the greatest number of advantages, with a minimum of drawbacks.

JOTTINGS FROM THE NOTE-BOOK OF A PHOTOGRAPHER'S ASSISTANT.

No. VII.

PHOTOGRAPHY, like a sensation play or novel, is a source of continual excitement to all who are within range of its influence; there is such a constant changing about that the votaries of this fascinating art must of necessity be ever on the alert if they would keep pace with its gigantic strides of progression. These changes, which ultimately assume the position of fashion, are led by some bold spirits that fearlessly strike into new tracks. The public follows fashion, and the more timid photographer must look alive and run with the public if he has a desire to keep his shop open. Happily he has but few trade secrets to contend against, therefore success will assuredly be his if he perseveringly seeks it.

We sympathize with the many who are striving to impart to their pictures those fashionable dark tones that are obtained from an adoption of what is called lime toning, and who, from numerous failures, are tempted to believe that success is derived from some secret source that is omitted

in all written instructions; to those we would say, feel assured there is no concealment. Failures are produced by a non-observance of some indispensable conditions, to produce those tones so temptingly described in the pages of the PHOTOGRAPHIC NEWS, it is absolutely necessary the prints be produced from a really good negative, clear in the shadows and perfect in all its details. The paper employed should not be too highly salted, and we are convinced that under all circumstances, the richest tones will be secured by an adoption of the nitrate of soda bath for sensitizing chiefly on account of the bright red colour it produces when the paper is exposed to light. When associated with lime, the gold precipitated on a dead surface assumes a hue anything but agreeable to an educated eye; but with a warmly tinted foundation, the deposit acts as a subduing glaze through which the colour beneath penetrates, imparting that richness that forms the chief characteristic of properly managed lime toning.

In attempting to produce black tones with the old alkaline solutions (so called), an unpleasing inkiness generally presents itself, though with less exposure to their action, a colour is imparted to the prints, which, before fixing, appears everything that can be wished for, but one moment's contact with the hypo, and the promising hue is vanished for ever, simply because this fugitive colour is imparted by chlorine in its secondary formed union with silver reduced by the action of light, a substance that is soluble in the fixing solution. The combination last alluded to has given birth to an error that is entertained even among high authorities, because a certain portion of silver is displaced from the paper's surface, during ordinary toning operations it is considered that such a result must necessarily ensue in order that the gold may take up its abode on the ground rendered tenantless by the ejected silver, and that toning action can only proceed under those conditions. To prove the fallacy of this mode of reasoning, it is only necessary to give our method of toning a trial when it will be found that with the absence of free chlorine, bleaching influence is removed, and in spite of a liberal allowance of acid roaming at large in the solution, tones can be secured that will pass unscathed through the ordeal to which they are subjected during the process of fixing, MM. Davanne and Girard notwithstanding. To secure the above described results, we proceed to construct our toning solution as follows:—A stock bottle containing 8 grains carbonate of soda to the ounce of water, is laid aside in a convenient corner; on the same spot lies another bottle, in which is placed a saturated solution of chloride and carbonate of lime, allowing the excess of both substances to remain precipitated in the bottles; when ready for toning operations, we add to each grain of gold 10 minims of the soda solution, and on this mixture is poured a small quantity of boiling water to drive chlorine in a direction where it is unable to practise its mischievous tricks. So soon as the yellowness disappears, the mixture is thrown into the toning dish, and the necessary quantity of solution is made up with pure water, allowing about a quart to the grain of gold, from two to three drops to the last named quantity of the lime is then filtered into the dish, and we are ready for work. The solution may be used continually instead of fresh water each time, and during cold weather double the portion of gold above named may be added with advantage. It is best to tone all the batch of prints at one time: like Parkinson's formula, it moves slowly, and therefore cannot injure by causing untuned spots, if the prints are kept turned.

A bath thus prepared is decidedly acid, although from the quantity of water used, the particles are so widely separated by dilution, their presence remains undetected by ordinary tests; but if its acidity is doubled, it is only necessary to test the solution in a more concentrated form; indeed, without a liberal allowance of acid, the bath refuses to work, and from this fact we are able to judge the necessary quantity of the alkaline agent to be applied, and non-toning when the proper allowance of gold is present, usually means

too much soda. Printing must be carried no further than required in the finished picture, as it strengthens rather than bleaches in the solution we have described; and in toning the same conditions must be observed, as the colour imparted does not change in the fixing bath. Before fixing, the prints should be first passed through a water containing a small quantity of carbonate of soda, another liberal allowance of washing, and fix in the usual manner.

The part played by lime in toning would be difficult to decide. One thing is certain, where that substance is employed, if the excess of chlorine is first driven off by heat, the small quantity remaining makes no attack on the silver, as it does in the absence of lime, and the same results follow when an ordinarily prepared lime bath has got rid of its chlorine by long keeping. From these facts we are inclined to believe that the small quantity of chlorine liberated is absorbed by the lime ere it reaches the surface of the paper, hence the colour is imparted by the gold alone, which substance protects the print from further reduction when exposed to the fixing action.

And now, in conclusion, we would just observe that no royal road to photography exists. In offering formulas or directions, we do not promise invariable success to anyone, but to all who will master the principles we have done our best to lay down. We promise the ability to overcome difficulties which may present themselves. In our experience we find in printing operations materials for continual study. Every day brings to light some new difficulty, whose character can only be detected by close observation, and whose dangerous tendencies can be conquered only by means that are based on scientific principles.

In concluding our first series of "Jottings," we would just observe that, from motives of fair play, we have refrained from recommending the materials supplied by any dealer; but should the cause of failures arise from defective paper, we are willing to supply the name of our favourite maker, by directing, under cover to us, to the office of the PHOTOGRAPHIC NEWS, with a stamped envelope for a reply.

ON TONING PAPER POSITIVES.

BY C. OMMEGANCK.

ALTHOUGH the auro-cupric bath we lately recommended has given results superior to those obtained by every other preparation, we shall, notwithstanding, give some indications respecting two other very useful formulæ, because a great many photographers, having acquired a certain experience of these two formulæ, determine not to abandon them.

The two formulæ in question are, 1st, that of acetate of soda, and, 2nd, that of hypochlorite of lime.

Gold Bath with Acetate of Soda.

Water	...	1 litre	...	35½ fl. ozs.
Acetate of soda	20 to 30 grammes	300 to 464	grains.	
Chloride of gold	...	1 gramme	...	15½ grains.

The acetate mentioned above is the crystallized acetate ($C^2 H^6 O^3, N a O + 6 HO$)=139: it contains, as may be seen, six equivalents of water: we can employ with advantage the anhydrous acetate of soda (twice fused), first in its water of crystallization, and afterwards submitted to an igneous fusion; it has the same formula as the preceding, minus the six equivalents of water ($6 H O$): the sum of the constituent equivalents, or its total equivalent, is 85. Between these two salts the relation is therefore as 139 is to 85, or, in round numbers, as 3 is to 2; therefore 30 grammes of crystallized are equivalent to 20 of fused anhydrous.

Commercial crystallized acetate of soda is slightly alkaline; the fused acetate is ordinarily very strongly so.

The preparation is made by dissolving in the water first the acetate and then the chloride of gold. Decoloration takes place slowly, and the bath is not fit for use until the morrow, and sometimes even four or five days after the pre-

paration, according to the state of the atmosphere, the nature of the paper, the neutrality of the nitrate bath, and also the more or less alkaline state of the acetate of soda. This bath usually disengages a very strong odour of acetic acid, and gives an acid reaction with litmus paper; it transforms into acetate of silver the traces of nitrate still remaining in the paper at the moment of immersing the proofs; acetate of silver is quickly sulphurized by contact with the hyposulphite.

The proofs at the moment of being taken out of the toning bath, have an odour of acetic acid: they really are acid; when immersed in this state in the bath of hyposulphite of soda, they assume a beautiful black tone; but they are exposed to an energetic sulphurisation, and subject to rapid deterioration. By washing them in abundance of water before fixing, we can, up to a certain point, palliate this evil. A washing in water containing a minimum quantity of carbonate of soda, neutralizes, it is true, the free sulphuric acid, but may cause many other inconveniences, among others that of causing blisters upon removing the albumen from the surface of the paper.

The addition of carbonate of soda to the gold bath, prescribed by some, will be the best remedy; but its practical effect, according to our experience, is to render the acetate entirely superfluous. The partial substitution of phosphate of soda for one portion of the acetate of the same base, for example, 15 grammes of the one to 15 grammes of the other, gave very good results; but in our eyes it presents the objection of uselessly complicating the formulæ, and of augmenting, without motive, the collection of photographic chemicals.

Bath of Gold and Hypochlorite of Lime.

Water	4 litres	...	141 fl. ounces
Carbonate of lime	...	10	grammes	...	154 grains
Hypochlorite of lime	...	1½	"	...	23 "
Chlorite of gold	...	1	"	...	15 ⁴ / ₁₀ "

Preparation. Put the carbonate and hypochlorite of lime into a mortar, and add sufficient water to form a creamy paste, then add the chloride of gold, and triturate together until an intimate mixture is effected, then leave it to repose for a quarter of an hour to an hour, according to the surrounding temperature, or as the quality of the paper is more or less subject to a corrosive action in the gold bath; then it is stirred into a litre of water, and the solid portion is allowed to deposit; it is then filtered, and the other three litres of water are added; this is when it is required for immediate use; when it is proposed to keep it for some days before using it, the quantity of water is diminished one half, the other proportion remaining the same. If a considerable time elapses, it may be that the bath will not tone at all; but the addition of 2 or 3 drops of the 10 per cent. solution of chloride of gold will render it active.

On removal from the gold bath, the proofs must be washed in two waters, or in one only, if very abundant. This bath is the most economical we know of, as to composition, be it understood, but not always as to use, it requires many precautions for the good preservation of the proof, which must be printed very strong, without which the half-tones will be lost.

Without washing the proof previous to immersion in the hypo bath, it causes sulphurization, produces sulphide of silver, and a disengagement of sulphurous gas, &c., and proofs that will not remain permanent.

It is often complained that toned proofs turn brown in the hyposulphite, without the tone returning after the solution of the salts of silver. Various causes may lead to this much dreaded result.

However, they all end in a too superficial toning. The following are the principal circumstances under which they may be produced.

Paper that has been nitrated a very long time—proofs kept a long time before being toned—paper moist at the time of printing—paper become slowly humid by exposure

to the atmosphere between printing and toning—silver bath too weak or too strong in nitrate of soda or ammonia, in consequence of long use—paper dried too slowly after contact with the silver bath or left to dry spontaneously in winter. The paper must be dried in less than an hour, and by artificial heat if necessary, interposition of humid paper or flannel behind the positive paper during the printing, and, lastly, and most frequently, a bath too poor in gold, too much reduced by fear of corroding the proofs.

It may sometimes happen that we are afflicted with paper of bad quality, from the remnants of dealers' stock, or bad manufacture. Paper deteriorates with age, and even in a very short time if not kept in a very dry place.

In winter, the toning must take place in a very warm room, beside a fire. The operation may be advantageously performed upon a water bath, kept at a temperature of 68° to 77° F.

We shall add some advice for those who have found that our formula for the auro-cupric bath has a corrosive action upon the paper they make use of.

First, the bath may be prepared several hours in advance. In winter, the prepared bath may be put into a bottle, which is placed in a large jar or other convenient vessel containing water heated to 104° F., and left it in from half an hour to an hour, without, however, applying a source of heat to maintain the temperature at 104°.

We shall conclude by some very curious remarks upon the peculiarities encountered in the colouring of the paper.

Albumenized paper contracts a different hue, both in printing and in toning, according as the negative has been developed with iron or with pyrogallic acid; and, if developed with iron, if it has been intensified to a blue-black by a salt of mercury—if the printing has been performed in the sunshine or in the shade—and if the sun has sensibly warmed the negative or not—if the negative is varnished with white varnish or with brown, when the difference in the colour of the negative is not even evident to the eye—if the glass upon which the negative is taken is blue, yellow, green, or violet—if, being of the same composition, it is thick or thin—lastly, if the sensitive paper exposed to the sun is in repose, or put into rapid rotation. It might, however, be supposed that we should mention here the more or less vigorous coloration resulting in a given time, according to the different media through which the light must pass. This difference also exists: it would be useless to dwell upon it, unless we proposed to inquire into the various modes of producing it, and their causes. What we have endeavoured to point out is a difference of tone, the vigour of colour being the same.—*Bulletin Belge de la Photographie.*

DESCRIPTION OF A SELF-ACTING WASHING-CRADLE, WITH SOME OBSERVATIONS AND EXPERIMENTS ILLUSTRATIVE OF THE PROCESS OF WASHING PHOTOGRAPHIC PRINTS.

BY CORNELIUS HANBURY, JUN., F.C.S., ETC.

DURING the late beautiful summer I was induced to devote a little time to the practice of photography, after having laid it aside for nearly nine years.

I found that, during this long interval, some important improvements had been made in various parts of the collodion process. But, so far as I have learned, no great change has taken place in the general mode of washing prints, although the great practical importance of the operation early attracted attention, and numerous methods have in consequence been suggested for increasing its efficiency or diminishing the labour it entails.

The common plan of placing several prints in a vessel, through which a stream of water is allowed to flow, has always appeared to me very insufficient, unless some special and rather troublesome precautions are taken. I was therefore glad to find that similar views are expressed by Mr. Pouting in his instructive little work, entitled "Photographic

Difficulties." His remarks on the subject are so exactly adapted to my present purpose that I must request permission to quote them almost entire; as the words of an experienced, practical, and entirely independent witness, they have far more value than anything I could say on the subject. Mr. Ponting says (p. 102 *et seq.*):—

"There now only remains the removal of the hyposulphite of soda and silver; and perhaps this is the most troublesome and uncertain part of the whole process. * * * * *

"The only secure plan is so thoroughly and carefully to wash the print in abundance of clean water that it would be impossible for any soluble matter to remain. The way to do this effectually, with the least expenditure of labour in the shortest time is the problem to be solved. * * * * *

"The following is the method which the author has practically found to be the best, after eight years' experience.

"The print, being removed from the hypo bath, is held by two corners between the fingers and thumbs of both hands, the print hanging downwards, and is then passed under a stream of water issuing from a tap, and slowly moved to and fro through the centre of the stream; the upper edge of the print cuts the stream in two, a portion flowing over each side, so as to remove a very large quantity of the adhering hypo bath from the surface. A tray of clean water being provided, the prints are placed therein, care being taken not have too many at a time, or they will stick together so that the water cannot penetrate them. It will be necessary to move them about to obviate this. After soaking for 10 or 15 minutes

is as perfect as it is possible to be; and this may be effected in two or three hours. * * * * *

"An experiment was instituted to prove how long a time was occupied in changing the water in a tray by means of a running stream. A tray was filled with twelve pints of water, to which two ounces of ink had been added, and well mixed; water was then allowed to flow into it at the rate of three pints a minute. Not until three and a half hours had elapsed, and nearly eighty gallons of water had been used, was the colour of the ink entirely got rid of; and this, be it remembered, was without any prints to impede the flow of the water. There can be little doubt, therefore, that if the tray had been charged with a lot of prints, the water would not have been fully changed in three or four times the period; and unless the prints were moved, the probability is that the centre would scarcely be touched. This shows how difficult it is, by means of a stream of running water, to secure an effectual cleansing of the print."

The method of washing here recommended is, I presume, the most efficient that can be suggested, and is only open to the objection that it involves so large an expenditure of time and attention that persons printing on a large scale can scarcely be expected to adopt it.

The simple apparatus which I have the honour to bring before the Society this evening will, I believe, be found to afford all the advantages of Mr. Ponting's method, whilst its employment demands no more time or attention on the part of the operator than the most careless use of the common tray.

A description of the apparatus will best explain its action, as well as its structure and principle.

Fig. I represents the apparatus in perspective. A B is a gutta-percha trough to receive the pictures to be washed. It is divided into two compartments by the partition C.

or longer, the whole of the prints should be taken out in a body, placed on a glass plate, and set up on edge to drain; the prints, being wet, will readily adhere. The washing vessel having been rinsed out and supplied with fresh water, the prints, after being left about five minutes to drain, are to be separated one by one and placed in the fresh water. If this process be carefully repeated some six or eight times, there can be no doubt that the removal of the hyposulphites

D is a wooden tray carrying the gutta-percha trough.

E is a metallic axis attached to the tray, D, and turning in gndgeons fixed on a strong wooden frame, F. From this it will be seen that the tray, D, and the trough attached to it, will rock with the motion of a see-saw upon the centre E.

H is a cog-wheel, into the notches of which one stop, attached to the tray, D, works, and another attached to the stand, F, thus causing the wheel to advance a notch each time the trough makes a complete oscillation.

Fig. 2 shows the apparatus in section. The letters indicate the same parts in each figure.

I I are conical valves opening into the compartments A and B.

When the trough is made to rock, as either end descends, the valve in it is raised by striking at the point J within a pipe, which discharges from the two ends by a common orifice at G.

K is a moving counterpoise, formed by a number of bullets rolling in a metal tube, L L.

M, moveable diaphragms or shelves, carried in a loose frame fitting into each trough, upon each of which a print is to be placed.

Fig. 3 represents the diaphragms and the frame which carries them.

FIG. 3.

From the above description, it will be evident that when the axis of the apparatus is placed under a tap, if the water is allowed to flow, it will fall into the compartment which is uppermost (fig. 1 A), where it will accumulate until its weight causes that end of the trough to descend. When this occurs, the valve (fig. 2 I), will be raised, allowing the water rapidly to escape, from the lowest part of the vessel into the waste-pipe, and in a few moments each picture will be left lying on the inclined surface of a diaphragm to drain.

By the same movement the upper part of the partition C will be carried to the other side of the stream of water; and, consequently, it will now flow into the compartment B. At the same time, the weight, K, will roll by the force of gravity and place itself under the compartment which is becoming empty, where it will supply weight, in place of the escaping water, until the compartment B has received the quantity for which the apparatus is adjusted, when it will in turn descend, its valve will be opened, the weight will place itself underneath it, and A will again be filling.

By these movements, which will have once filled and emptied each compartment, the index will be moved on one division.

Thus the apparatus, when charged with prints, and placed under a stream of water, without any further attention, completely *changes* the water at definite intervals, allowing it to escape from the lowest part of the vessel. It exposes the prints *singly* to the action of the water. It *drains* them in an inclined position between each change. It *registers* the number of changes, and consequently the quantity of water passed over the pictures, thus enabling the operator to employ a definite and uniform amount of washing. And it causes sufficient motion among the pictures to prevent the adhesion of bubbles to their surface.

Experiment proves that, other things being the same, it washes in less than one-sixth the time of the ordinary tray, and with a proportionately smaller quantity of water.

The apparatus now shown has been made for me by Mr. Wood, of 74, Cheapside, who, with his usual skill, has excellently carried out my views.

Mr. Wood is prepared, I believe, to supply the apparatus of any size, and of the most economical construction.

In its simplest form, the apparatus may be made without

either valves or weight, merely having a hole at each end, through which the water may escape. But it then becomes necessary considerably to increase the length of the trough, and the angle through which it moves, in order to admit of the accumulation of sufficient water; and this is objectionable because the long descent causes a violent agitation of the water, and also because the water, whilst accumulating, lies too exclusively in the angle at the base of the partition.

These inconveniences are entirely overcome by the moving counterpoise, by means of which the angle of motion may be *reduced*, and the quantity of water accumulated between each change *increased* to any extent desired. The counterpoise may take various forms. I at first used a weight swinging, under the apparatus, at the end of an arm around a centre near one end of the axis E; but probably the cheapest and most convenient will be found to be a sufficient number of large bullets enclosed in a brass or tin tube, in which they can roll freely: as many of such tubes can be attached to the bottom of the trough as may be found necessary. In the small apparatus shown, mercury is substituted for the bullets; and it is placed in a glass tube in front of the trough, that its motion may be seen. One large ball will be found to produce an unpleasant shock, and the same disadvantage attaches to the swinging weight. Possibly a useful modification may be made, especially if a porcelain trough be desired, by prolonging the arm of the weight a little behind its axis, and there causing it to compress alternately caoutchouc tubes leading the waste water from the ends of the trough. No valves would then be required.

On a large scale it may probably be found advantageous to employ the swinging weight attached to a rod carried above the trough, parallel to the partition (C). The power of the counterpoise can then be adjusted either by its absolute weight, or by the height above the axis (E) at which it is placed, or by the length of the arm on which it swings, or, if sufficiently elevated and heavy, it need not swing at all.

If very large numbers of pictures had to be washed, the apparatus might take the form of a series of double troughs, placed side by side, along a common axis, each pair being supplied with water by a jet from a common supply-pipe placed, parallel to the axis, above them.

In the construction of the apparatus it will probably be found sufficient if the trough moves through an arc of 20° , which will give 18 divisions on the index wheel. The motion in the apparatus shown is 30° , and is unnecessarily great. It may be found useful to have a float-board to prevent the water slopping over when the full end descends. In the apparatus made for me, Mr. Wood has ingeniously added a second index-wheel in front of the first, but having one tooth more, and an opening in its face, which shows, one at a time, a second series of figures on the first wheel, and thus it very prettily records the number of revolutions of the first wheel; but such a provision is scarcely required.

I have tried numerous plans for keeping the pictures apart. My first attempt was to use straw mats of the kind employed for covering cream cheese. Then, with much trouble, I got some thin sheet gutta-percha corrugated so as to present a surface like the straws. Experiments soon proved that the plain gutta-percha without channels answered the same purpose and retained less water, and was less liable to injure the pictures; but it has the great disadvantage of adhering very closely to the paper after draining, and forming a mass which floats bodily, and only loosens again very slowly. Thus I was led to adopt diaphragms having an independent support. On the small scale, glass can be used. It may slide in metal grooves, such as are used for plate-boxes. On the large scale, probably tin plates may be used. The space between the diaphragms need not exceed the thickness of patent plate glass. As they occupy an inclined position, when the water enters, it drives the air before it, the stronger solution gravitates to the lowest part of the trough; and as no wave motion can occur in such a cell, when the water is discharged, it ebbs out, leaving the paper smoothly laid on the incline to drain. The support of the diaphragms directs

the water flowing from between them towards their ends, and thus prevents any tendency to float the prints down their inclined surfaces.

If the shelves are not perforated, the prints have a slight tendency to cling to their under surfaces. But when diaphragms of perforated zinc are used, the papers rise and fall with the water, and float about in the little space between the shelves with perfect freedom, leaving apparently nothing to be desired. Unfortunately, however, zinc acts on the pictures and cannot be used. Probably, ebonite similarly perforated will be found to answer. Should it prove expensive, or otherwise unfit, a material perfectly suited for these diaphragms will be a desideratum.

If we now imagine Mr. Ponting's experiment with the ink to be repeated with the arrangements here recommended, we shall see at once that the first change would empty out the ink, the second would rinse the trough, and the third would show no trace of it; and thus a few pints of water and a few minutes in time would effect what he found to require in a stationary tray 80 gallons of water and 3½ hours.

But it is worth while to consider a little more closely, how the removal of soluble salts from the tissue of paper is really effected.

If we could cause streams of water to permeate every pore and to carry with them by mechanical force all the matter which could be either dissolved or suspended, then the process of washing would be definite, absolute and perfect, and the duration of the operation would only depend on the rapidity of the streams. But we possess no such power. In the first place, a stream of water but very slowly removes water which is already adhering to a solid. Every chemist knows how surprisingly insufficient even the repeated rinsing of a test-tube often proves. In the circulation of the blood through the capillaries, and in the flow of any fluid through a small tube, the liquid immediately in contact with the pipe appears to be stationary, and is known to physiologists and physicists as the *still layer*. The phenomenon is no doubt due to the fact that particles of water are more powerfully attracted by those of most solid bodies than by each other, as is shown by the concave surface assumed by water in all ordinary vessels.

These considerations show how easily the particles of water in actual contact with a picture may allow others to flow over them without becoming themselves detached. By draining, however, a large portion of this adhering water is removed; and hence every experiment shows a much larger proportion of hyposulphite in the last drainings than in the bulk of the water discharged at each change. But for the removal of the hyposulphites from the *tissue* of a picture we are wholly dependent upon the property which soluble salts possess of *diffusing* themselves through the solvent which surrounds them; and thus it is that the process of washing becomes indefinite, comparative, and, in theory, only approximately perfect. All we can do is to secure the conditions most favourable for diffusion.

What these conditions are is thus stated by Professor Graham, whose beautiful researches almost created this important branch of chemical physics. He says, "The general law of diffusion appears to be this:—*The velocity with which a soluble salt diffuses from a stronger into a weaker solution is proportioned to the difference of concentration between two contiguous strata,*" (Graham's Elem. of Chem. ii. 608). The arrangements just described appear to secure these conditions with the least possible labour; but I am anxious that it should be clearly understood that *time* must ever remain an important element in any process depending on diffusion.

Each change of water subdivides the quantity of the salts in solution, and at first greatly weakens the solution left in the paper; but for the very reason, in accordance with the law just stated, diffusion goes on more and more slowly, the difference between the solution in the paper and the contiguous stratum of pure water becoming less and less. Hence the great practical importance of using a moderately small stream of water, and of continuing the process for a

considerable time after all appreciable traces of the salts have disappeared.

The principle of applying water in the most efficient manner to some primary purpose by making use incidentally of its own mechanical power, on some plan analogous to the one I have adopted, may probably admit of application in other processes. But if, by lessening the labour of the conscientious and the temptation of the unscrupulous, the suggestions here made should promote the better washing of photographs, and thereby the reputation of the art, my hopes and intentions will be fully realized.

Proceedings of Societies.

LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting of this Society was held in King's College on the evening of Tuesday the 1st inst. COL. STUART WORTLEY in the chair.

The minutes of a former meeting were read and confirmed.

The CHAIRMAN said, in accordance with the 7th rule of the society, the names of retiring officers would now be read together with those nominated by the council to fill their places. The rule was as follows:—All officers of the society shall be annually elected, with the exception of the Secretary and such members of the council as may not go out of office by rotation or otherwise. The mode of their election shall be by ballot. The council at the ordinary meeting in December in each year shall declare the names of the members of council whom they recommend to retire, and lay before the society the names of those whom they have selected to supply their places. They shall also declare the names of the other officers they recommend for re-election, and cause a list to be suspended in the meeting-room. In the event of any member of the society being desirous of proposing other names than those recommended by the council, a written list of the same shall be delivered to the Secretary at or before the ordinary meeting in January; and the same shall be read from the chair, and publicly suspended in the society's room, with the list recommended by the council; and no member shall be eligible for election into the council unless he shall have been proposed in the manner and form above specified.

The names of retiring officers and those proposed, were the Lord Chief Baron, President, who was proposed for re-election. Mr. Vignoles, Vice-President, Col. Stuart Wortley being proposed in his place. Mr. Hamilton, Hon. Treasurer was proposed for re-election. The retiring members of the council were Messrs. Vernon Heath, Peter Lo Neve Foster, H. Pollock, Hennah, Col. Stuart Wortley, and Lord Henry Lennox. In their place were proposed for election or re-election, Messrs. Elphinstone Underwood, J. P. Gassiot, Josiah Slade, Sebastian Davis, H. Pollock, and the Hon. Warren Vernon. Any members of the society desiring to nominate other officers, must do so at the January meeting.

The SECRETARY called attention to some charming figure studies and examples of double printing, by Mr. H. Cooper, Junr., taken in the open air, chiefly by Dallmeyer's No. 1 triple lens, which were much admired; also to some of Mr. England's beautiful views of Swiss scenery, taken during the past summer.

Mr. SPILLER then read his paper on "Photography in its Application to Military Purposes," which was profusely illustrated with examples which were examined with great interest. No discussion followed.

The CHAIRMAN, in proposing a vote of thanks, remarked, that, as Englishmen, they were all deeply interested, and himself pre-eminently so, in the subject Mr. Spiller had described so ably. He had to announce that, at the next meeting, Mr. S. P. Smith would bring before the members some further particulars regarding the alleged photographs of the Eighteenth Century. He trusted that all the members would interest themselves in gathering together any evidence bearing upon the subject, and enable the society to pronounce definitely upon the subject, whether this country could claim the origin of photography at the early date claimed, or whether hitherto received claims remained undisturbed.

The following gentlemen were elected members of the society:—Messrs. Howe, Goslett, R. H. Michell, W. Rowland

Holyoake, C. A. D. Halford, Sydney Smyth, G. Hooper, F. G. Eliot, Major Gresley, Stanfield Grimshaw, Douglass S. P. Winsor.

The meeting then resolved itself into a conversazione, and finally adjourned to the first Tuesday in January.

THE AMERICAN PHOTOGRAPHICAL SOCIETY.*
FIFTIETH MEETING.

THE Society held its first meeting after vacation on Monday evening, Oct. 12th. in the University Chapel; the president, Prof. DRAPER in the chair; Mr. O. G. MASON was appointed Secretary *pro tem*. There was a full attendance of members.

After some miscellaneous business, Dr. HENRY DRAPER read a paper on Celestial Photography (see p. 550). The paper was illustrated by a mammoth photograph of the moon.

Mr. RUTHERFORD said he would only rise for a moment to give his testimony to the exceeding excellence and remarkable success of the photograph presented. He considered himself some judge of the matter, having been engaged in photographing the moon since 1857, with more or less results; and his experience taught him it was one of the most difficult things that could be attempted, because it involved the union of so many conditions on the same point and on the same occasion, before a fine result such as this could be obtained. In the first place, you must have a large, fine instrument. The instrument here used was a work of great ingenuity, patience, and skill; and Prof. Draper, in making it, had not only accomplished the photographic result before them, but had constructed a telescope of great power for astronomical purposes. Next, there must be the cleanest and most rapid application of photography, and then a very true and exact motion of the plate. They might well congratulate themselves that one of their own members, with instruments made by himself, had been so successful in producing the remarkable piece of excellence exhibited.

Effects of Light.—Mr. JOHN JOHNSON said it had been suggested to him, some time since, whether equal times gave equal photographic effects; and he exhibited some specimens produced by an ingenious contrivance, tending to show the negative of the proposition. There were also shown some interesting experiments on the different shades produced by various coloured glasses, exhibiting all grades of action, from extreme dark to none at all.

Influence of Light on the Growth of Plants, through coloured media.—Mr. JOHN JOHNSON read a paper, giving the result of experiments on this subject, made during the summer.

The PRESIDENT said that Mr. Johnson had directed their attention to two very interesting points, to which he would briefly refer. The first was, "Is the germinating or sprouting of seeds influenced at all by the colour of light that happens to fall on them?" That is, will seed germinate better under violet, yellow or blue? He has disposed of that, and I think, correctly. Indeed, when you come to look at the matter, every one must be convinced that light, in so far as its colour is concerned, has little or nothing to do with the germination of a seed. The simple fact that we place seed under a layer of earth is tantamount to an exclusion of light. The seeds germinate in the darkness, and the light has nothing to do with it. The second point is, what are the conditions when the plants are fairly growing? Does one kind of light prove to be more favourable to the development and growth of a plant than another? The experiments made settle that question (if it needed settling) in the most satisfactory way. Some kinds of coloured light are far more favourable to the growth of plants than others. In the book of Prof. Monekhoven, presented this evening, there is the strangest mistake; he affirms that it is actinic light (*i. e.*, the violet rays), which operates best in developing growth. Such is not the fact. It is light not actinic at all—orange, yellow, and green rays—which promotes the growth of plants; the violet, in the experiments I made, seemed to have no action whatever; the plants turned white, looked sickly in appearance, and very soon died. But it was very different with those growing under orange, yellow, and green rays.

Preserving Plates.—Mr. C. W. HULL produced a large-sized photograph taken from a tannin plate eighteen months old before exposure.

Col. PIKE, and other members, made some remarks showing

* Condensed from the *American Journal*.

the advantage of the dry process in preserving plates. A great deal depended upon thoroughly washing the plates.

Some observations were made on micro-photographs, which Mr. Rutherford characterized as mere toys, and hardly worth the trouble of mounting, after all your labour.

New Members.—W. H. Gilder, H. J. Newton, H. L. Boltwood, Wm. Vollmer, and A. Bogardus, acting members. Prof. John Towler, of Geneva, N. Y., a corresponding member.

Adjournment.—The Society adjourned to the second Monday in November.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, December 2nd, 1863.

M. DE CONSTANT DELESSERT, a skilful amateur photographer, residing at Lausanne, has obtained instantaneous proofs by means of the double sulphate of iron and ammonia. He had a choice between a half-plate German lens of short focus and very quick acting, and a French objective, four inches diameter, of long focus, and comparatively slow acting, since it required 20 to 30 seconds' exposure in the operating room. To obtain rather large dimensions, he took the French objective, and with as short an exposure as possible, by opening and closing the objective with a hand screen, he obtained negatives with objects in motion. What particularly characterises these pictures, remarkable for their size, is the accuracy of perspective, and, in some, the sharpness of the distances. M. de Constant Delessert thinks that there will be an advantage in these conditions, in replacing objectives with short focus, which often give harsh and hard pictures, by those of long focus, which give greater delicacy. He developed the pictures with a bath of double sulphate of iron and ammonia, which gives great rapidity, and especially permits of slowly developing the picture by bringing out the shades without injuring the high lights. Perhaps, with the addition of formic acid to the sulphate of iron, still greater rapidity may be obtained. We purposely raise the question of formic acid, which has not yet been tried by many operators, and which has given contradictory results in the hands of several experienced operators. It would be very interesting to compare proofs of large dimensions obtained by this method with the charming specimens produced by M. de Constant Delessert.

M. Meynier, of Marseilles, to whom we are indebted for the introduction of the new fixing salt, has announced a new toning bath. It is obtained by dissolving 6 grammes (92 grains) of sulphocyanide of ammonium and 1 gramme (15 grains) of chloride of gold in a litre (35½ ounces) of water. We may remark in this place that the sulphocyanides now take a decided rank among photographic materials, their price is moderate, and their employment cannot be too strongly recommended, especially as they will supersede cyanide of potassium, from which so many fatal accidents happen.

Generally speaking, toning baths give better results after being made some hours than when newly prepared. M. Ommeganck, of Brussels, has recently given a formula for a toning bath containing both chloride of gold and copper, which, he states, works well as soon as made. This bath consists of—

Water	1 litre.
Chloride of gold	0.5 gramme
Deuto-chloride of copper	0.1 "
Carbonate of soda, until an alkaline reaction takes place.				

M. Ommeganck claims another advantage for this solution, that the tint of the proof is influenced by the presence of the chloride of copper; with a small proportion of this salt the tint remains black, but if the quantity be increased, it becomes blue grey. By varying the relative proportions of the salts of gold and copper, all the intermediate hues may be obtained.

REDUCTION OF RESIDUES BY LONDON REFINERS.

DEAR SIR,—We notice in your journal of the 27th inst., a paper written by a Mr. Jacob Ewing on the subject of "Photographic Residues," purporting to give Mr. Maenab's experience of the "respectable London refiners."

Ranking, we hope, as one of the "respectable" (though not advertising) London houses, and as having received a communication in December last from this same gentleman, we think it would have been more fair on the part of Mr. Ewing to have stated that the experience then obtained was not of the same character as that now detailed by him.

An inquiry (but no sample) reached us from Mr. Maenab, "What would be allowed in nitrate silver in exchange for 350 ounces of dry chloride?" The answer given was—"If perfectly pure and dry you would receive in exchange probably 380 ounces;" but a suggestion was made that the whole should be first reduced to ascertain the exact value. (This suggestion was rendered necessary from the fact that chloride of silver in bulk is so liable to variation from the kaolin and other impurities which are often thrown in with it, some portion of a parcel frequently yielding 74 per cent., while another portion will not give 50 per cent. of metal). This amounted to an offer for the chloride of 3s. 8½d. per ounce avoirdupois, or 4s. 0¾d. per ounce troy. (Chloride of silver is properly bought and sold by avoirdupois weight, as nitrate of silver and all preparations of the precious metals are.) Now the intrinsic value of chemically pure chloride of silver is 4s. 1½d. per ounce troy; this offer, therefore, left just ¾d. per ounce to cover the refiner's expenses of reduction and his profit.

The calculation made is here given—

350 oz. of chloride at 3s. 8½d. per oz. avoirdupois.	=£61 17 2
380 " nitrate " 3s. 5d. " "	=£54 18 4

In justice to the "respectable London refiners" (of whom we hope there are many), we trust you will find room for the insertion of this statement.

Mr. Ewing's letter reads too much like an advertisement in favour of Coghill's refinery.

If this parcel of chloride is the same as that referred to above, it will appear that Mr. Maenab realized £55 for what £64 18s. 4d. had been offered by one of the "London refiners."

The system of asking refiners to buy residues at a valuation, without previous reduction, cannot be too much depreciated. In justice to themselves they must allow a certain margin as a protection from loss through inferior residues. We think it would have been better taste to have given the refiner who offered 2s. per ounce for the chloride the credit of having made a mistake, either in halving the result of his calculation, or in being guided in his offer by some erroneous impression. We imagine that no one would knowingly offer 2s. for what was worth 4s.—certainly, not a "respectable London refiner."—We are, dear Sir, yours very truly,

MATTHEW BOLTON'S CAMERA.

SIR,—I read with interest the correspondence published in the NEWS of the 20th inst., and I send you some additional particulars and information which you are at liberty to publish.

There came a request some time ago from Mr. Powell to my brother to make a search for the old camera, but no tidings have as yet been heard of it; inquiries have now again commenced.

Mr. Powell is an intimate friend of mine, and showed me the old camera when he had it; and having then had some considerable experience in photography, I will give a description of it in the state I saw it.

The body formed a cube of about 12 inches each way; out of the front projected a square tube which would slide in and out, seemingly to get the "focus" of the lens. This was about 4 or 5 inches square, and when pulled out to the full extent

projected some 12 or 14 inches in front, like a long nose. It tapered off at the end, and terminated with a circular piece of wood having a round hole, turned in the middle, of 2½ or 3 inches diameter. There were no marks of screw holes on this piece of wood, as if any metal mounting had been screwed on, but the edges were levelled off, as if to simply push the lens in it. There was no lens in when I saw it, nor did Mr. Powell say that he had one with it.

The back part of the camera, which would receive the paper or silver plate, was devoid of fastenings for that purpose. I do not know if there were any in when Mr. Powell first got possession of it; but at the time I saw it, he had been putting some fastenings of his own to make his experiments.

This was its general form.

While looking at it at the time, to see if it could be of use as a camera, I thought it could be made serviceable by simply placing a groove at the back for the reception of a dark slide, and screwing a lens in front; I noticed that light would get through where the slide fitted in the front, but that would be remedied by throwing the focussing cloth over it.

In the letters No. 4 and 11 of Mr. Price's, there is a seeming contradiction. In No. 4, Mr. Powell speaks of it as "a most excellent instrument." In No. 11, it is described as "roughly made." The extreme age of the wood—unvarnished oak—gave it a lumbering look, but when examined, it was carefully and well made, not of course to bear a comparison with a modern camera.

I may add that Mr. Powell is very clever in making ingenious and accurate models of any object. I will warrant that he will make an exact model of the old camera, if paid for his trouble.

THOMAS KIRKBY.

Trentham, Staffordshire, Nov. 24, 1863.

Talk in the Studio.

STEREOSCOPIC PICTURES BY MR. GOOD.—We have received from Mr. Frank M. Good some very charming stereos of scenery in Hampshire, Dorset, and Devonshire. Many of the landscapes are enriched with well-disposed figures. There are also some instantaneous views of the sea and shipping, with fine clouds and sky. The selection is good, and the manipulation very satisfactory, giving rich vigorous pictures. Mr. Good uses bromo-iodized collodion, with iron development, and Dallmeyer's stereo lenses.

GREY VIGNETTES.—Mr. Watson, of Yarmouth, for whom a correspondent claimed, a short time ago, the origination of the vignettes which graduate into a flat grey tint, instead of white paper, has sent us some very fine examples of this class of work. As we before remarked, this method is of much older date than Mr. Watson's practice of it. Without any reference to the question of origin, however, these are exceedingly fine specimens of the class of work, and charming photographs altogether.

AUSTRALIAN PHOTOGRAPHS.—Messrs. Moira and Haigh have recently brought under our notice a very interesting series of photographs of scenery in the gold fields and other parts of Australia. They consist of about 150 stereoscopic subjects, and about 100 larger pictures. As they are not intended for publication, Messrs. M. and H. place them for the inspection of all

interested in Australian scenery and associations, at their rooms in Seymour Street, Portman Square. We are informed that the temperature frequently reached 120°, but that this caused no especial photographic difficulty, which the use of a weak nitrate bath and manipulating care did not easily overcome.

WEAK PRINTING BATHS.—Messrs. Sawyer and Co., of Newcastle-on-Tyne, have sent us some rich vigorous prints produced with a 35-grain silver bath, containing, as well, 40 grains of nitrate of soda, which they have been working with great satisfaction and success. They are especially forwarded to us as specimens of the work of the No. 1 B card lens with full aperture, and are surprising in this respect, as examples of definition.

PHOTOGRAPHIC FORGERY.—The conviction of Rinaldi, a Swiss, convicted of using photography to forge an Austrian note, has recently been affirmed on the ground that a photographic copy is a forgery, according to the meaning of the Act.

To Correspondents.

- E. S.**—The brown stains occurring on the application of the tannin arise from imperfect washing, and indicate the presence of free nitrate still in the film. These stains generally occur near the corner, and often at the end where the collodion is thickest. Some samples of collodion require much more washing than others, from retaining the free nitrate with much greater tenacity. 2. We have not tried any printing experiments very lately, press of duty and bad weather not permitting. Have you observed whether the mottling is produced by the removal of patches of the albumen, or by the absence of silver? 3. Some of the bargains advertised are doubtless genuine, whilst others may be deceptive. Persons purchasing under such circumstances risk something, to save something. Good articles may by chance be obtained at a low price; you can only be certain of excellence by paying its market value. 4. About 35 grains of chloride of sodium will be required to precipitate 100 grains of nitrate of silver.
- J. S.**—The estimation of the quantity of gold in a given solution is a very delicate operation. The hydrometer test is much too rough for practical purposes. It is one thing to ascertain whether a silver solution contain 50 grains or 60 grains to the ounce, but a different affair to ascertain whether a gold solution contain one grain or three. Mr. Francis Sutton recommends oxalic acid as a test, which precipitates the gold and is itself decomposed, one equivalent of gold decomposing three of oxalic acid. The use of protosulphite of iron has been recommended, but it is difficult to ensure the entire absence of a persulphate. The best practical test for a photographer is toning capability of a solution. Mr. Hart's volumetric apparatus is intended to be used with gold solutions. We are uncertain, at present, of the re-agent he intends to be used.
- W. S.**—Streaks in the direction of the dip arise from various causes. The presence of organic matter, or of accumulations of ether and alcohol in the bath, which must be got rid of by sunning and evaporation. A slight tendency to alkalinity, which may be removed by adding acid. The bath being rather strong, which may be remedied by dilution. The use of a new sample of cadmium collodion will sometimes cause it. Moving the plate laterally frequently, whilst in the bath, is a good thing when the tendency is present.
- N.**—Amber varnish, benzoin varnish, or dammar varnish, may be applied cold. The first is the hardest. The other two are slightly friable, and are apt to become tacky with the heat of sun printing. 2. Dilute gum water, or dilute albumen will preserve the film when it has a tendency to crack or peel. 3. We are not quite sure of your meaning when you refer to a paste for "mounting negatives." We have not used dextrine as a paste at all ourselves. It is, however, soluble in cold water. We have for some weeks past been trying gum tragacanth dissolved in 4 or 6 parts of cold water. It makes an admirable paste.
- X. Y. Z.**—We have had no experience in the cleaning of rolling presses; but should imagine that cleaning with a little rouge, or whiting and oil, would suffice, taking especial care to remove, by a subsequent dry polish, all traces of oil.
- J. KINGSLEY.**—Your vignettes, Nos. 1 and 2, are best; No. 3 is under-exposed and over-intensified; in No. 4 there is too much diffused light. To get a better tone print deeper and tone deeper.
- OLD SUBSCRIBER.**—We shall take an early opportunity of testing the bath. We do not think there is any danger of it not keeping, as we have kept it in solution for months, but have not tried it without the addition of some other salt.
- CANTAB.**—Where the albumen is removed by the bath of nitrate of silver and nitrate of soda, it is, we presume, from the use of a sample of the latter having a strong alkaline reaction. The addition of a few drops of nitric acid will probably remedy the evil.
- A BEGINNER.**—If the nitrate of silver stains have been on the floor some time, it will be very difficult to remove them. The application of a little tincture of iodine or hydrochloric acid followed by strong cyanide may effect it. 2. The lime toning bath is as economical as any you can use.
- DAK FOG.**—You can precipitate your bath as a chloride with common salt, and then reduce the chloride to the metallic state as we have often described.
- YOUNG PHOTO.**—If the camera be properly blackened inside, the rays reflected from its side will not produce much effect. When the body of the camera is extended, you may use the stop you describe, but take care that it is large enough to allow all the rays forming the image to pass through, and that it is quite black and reflects no light itself. 2. The only plan to get rid of texture in copying is to roll the print well; be careful in the lighting. 3. The allusion to taking views larger than portraits means that the front lens of the portrait combination can be unscrewed and used as a single view lens. 4. It is necessary to size albumenized paper with gelatine or

isinglass before applying oil colours. 5. We have no experience in the use of the liquid colours.

- G. AVERY.**—The long focus, No. 1 B, would probably answer your purpose, but requiring, as you state, 14 or 15 feet, you would be cramped for space in a room of 17 feet. In such case we should prefer to use the No. 1 B ordinary, which will doubtless answer your purpose satisfactorily, and give excellent results. You will not have distortion as you fear. 2. If the stop were used in contact with the lens, absolutely cutting a portion away, your argument would be more to the purpose; but the stop is always placed in such a position that all the lens is really used. The question is too large a one for general discussion here. The question of small lenses v. large ones has been the subject of much discussion in years gone by.
- H. B. LITCHFIELD.**—You can only obtain information as to all the photographs registered by application at Stationers' Hall. The list in our pages simply refers to those entrusted to our publisher for entering. 2. The copyright is secured for the life of the owner, and seven years after his death. 3. There is no object in registering a photograph of a picture which is not copyright, as any one else may copy the original. 4. Read the Copyright Act.
- ACETATE.**—The silver in old developing or intensifying solutions will generally precipitate in a metallic form, spontaneously; any remaining in solution may be thrown down as a chloride. 2. The best acetate formula is 1 grain of chloride of gold, and 30 grains of acetate of soda, in 6 or 8 ounces of water, made two or three days before use. 3. There is no necessity for using salt in the washing water. Three or four changes of water will remove the bulk of the free nitrate, and the use of salt is often a hindrance to toning. 4. One ounce of hypo in 4 or 5 of water will give a solution quite strong enough for fixing.
- R. P. H.**—Mr. Robinson's pictures are on albumenized paper. 2. The period of the Photographic Exhibition is not yet fixed.
- A BELFAST READER.**—The cause of your negatives cracking is, doubtless, damp. Any trace of chloride in the last washing water, after fixing the negative, or imperfect washing, leaving trace of the fixing salts in the film, would, in damp weather, favour such cracking. M. Claudet recommends, as a partial remedy, to rub the cracked negative with powdered charcoal or blacklead, with a piece of cotton wool, which, filling up the cracks, makes them print without showing the cracks.
- CONSTANT READER.**—We have never met with a case of the film leaving the plate after it is varnished. We should imagine that a dirty plate, or the presence of traces of hygroscopic salts in the film, must be the cause.
- D. DUNCAN.**—The Nos. of the PHOTOGRAPHIC NEWS out of print, and for which the publisher will give full price, are as follows:—6, 9, 41, 49, 53, 65, 76, 80, and 104.
- CLIFTONIAN.**—We cannot understand your experience. We have never had the slightest difficulty in using it. We have some now which has been made for months, which tones excellently. Your experience is isolated and anomalous. The addition of a drop or two of fresh chloride of gold solution would probably start the action and make the toning go on all right with the solution you now find useless.
- A YOUNG BEGINNER.**—The mode of treating a bath to remedy pinholes depends upon the cause, but the most common cause is the accumulation of lodonitrate of silver, and diluting and filtering is the proper remedy, afterwards making up the proper strength. 2. We do not understand the kind of stains you mean without seeing a plate. 3. About one-third of an inch stop will answer; place it in front about 1½ inch from the lens. In copying use such a stop as gives you satisfactory definition all over. About a 15-grain iron solution.
- WISLOW.**—It is impossible to give a rule for the "management of your light." It must be varied to suit varied sitters at various times of day, and in different states of weather. You must see that each sitter is properly illuminated. You are using too much light all round the sitter, and under-exposing and over-intensifying your negatives. 2. Use the acetate toning bath, and with good negatives you will get the tones you desire. 3. We have not tried either of the lenses you name, but believe them both to be pretty good of their class.
- ERRATA.**—In Mr. Barrett's letter in our last on "Transferring Negatives to Gutta-percha," the sentence in line 14 should read, "the bottle should be more than half filled with gutta-percha," in line 19, for "bearing" read "leaving."
- PAINTING BACKGROUNDS IN TINTS.**—We have received from Mr. Phillips a further reply to "R. A. S.," from whom he still conceives that he has received much less than justice. He now narrows the matter to one of personality, and is wishful to state his convictions as to the name and profession of "R. A. S." These conjectures are quite unsuited for discussion in our columns, and do not in any way affect the correctness of the opinions held by either party. "R. A. S." recommended backgrounds painted in black and white, or greys; and, in expressing this preference, did not recommend the production of anybody. Mr. Phillips recommends the use of tints, and has had an opportunity of justifying his preference. There the matter must rest, unless Mr. Phillips has more to say on the general subject, without reference to personal questions. Several Correspondents in our next.

A PHOTOGRAPHERS' RELIEF FUND.

THE rapid growth of photography, as a trade or profession, is, perhaps, unprecedented in the annals of industry. Within little more than the last decade of years it has grown from an amusement of the educated, or the occupation of a small number of professional Daguerrocotypists, in a few metropolitan cities, into an important branch of the industry of the world. The statistics of the art are not yet collated, but we risk nothing in stating that tens of thousands of persons depend upon its different branches for bread in this country alone.

Whilst it has been, and still continues to be, a fairly remunerative occupation to the many, the inexorable laws of political economy will affect it as they do all other trades. Demand for labour creates supply, with increasing supply must come competition, with competition decreased value; in short, it necessarily falls out that the mass of working photographers can only earn a fair living income. Photographers possess no immunity from accident, sickness, helpless old age, indigency. Life in the dark room is rather calculated to sap the foundations of health and vigour. Unlike many of the older industries, it has had no bequests from rich citizens, it has no almshouses or retreats, no fund or resource of any kind to which its unfortunate professors may apply for aid even in their utmost need. The question then forcibly arises, Has not the time come for the establishment of a Photographers' Relief or Benevolent Fund?

We do not pause now to argue the need. Cases have already arisen illustrating it. Specific appeal was recently made for Mr. Watson, who had lost his sight. This week we publish, on another page, an appeal which deserves especial consideration. The man who made photographic portraiture possible, who first introduced bromine into the art, and was one of the foremost amongst the early votaries of photography, is now, and has been for some time past, not only living on very precarious charity, but has been suffering absolute penury. With the instincts, education, and habits of a gentleman, he has shrunk from putting his own case before photographers, upon whom he has really strong claims. We have personal knowledge of the facts stated by Mr. Hughes in another page, and we are thus strongly confirmed by them in our conviction that it is full time a permanent Fund were established, to which such a man might appeal, without the natural hesitation which exists in delicate minds to ask for private charity. Such a Fund should exist, that personal and specific effort need not be invoked for each individual case which is necessitous and deserving. The proudest boast of this age and this land is, not its stupendous growth in science, art, or industry—its boundless knowledge—its almost unlimited powers; but that all these exist for the people at large, not for a few, as was the case in the civilization of empires which have crumbled into dust. It is the recognition of the claims of all, of the universal brotherhood of mankind, which constitutes the essential greatness of the age. Out of this recognition has

arisen the wonderfully perfect organization of benevolence which exists in every form. There is scarcely a phase of want, misfortune, or suffering, which is not met by its special and organized mode of relief. With the new want has come, hitherto, the new fund; and we feel that the importance of the subject to which we now ask attention, has to be but once considered to induce spontaneous recognition and prompt action. Until now its need has scarcely existed. Cases have just begun to arise, but, with the progress of time and the further growth of the art, they may be expected rapidly to accumulate, and will require an accumulating fund to meet them.

We should be glad to see this matter practically emanate from the Photographic Society, or at least be in some way associated with it. We think that an organization formed for obtaining and dispensing such a fund might claim the sanction and patronage of the highest person in the land; we feel assured it would obtain the aid and sympathy of all classes of photographers, from the highest to the lowest. We need not here plead precedents, such as Literary Funds, Dramatic Funds, Printers' Pension Societies, and a host of others, their existence is too well known to need repetition. Such an organization should know no class interests, no party feeling, no petty clique jealousies. We should like to see the hearty co-operation of all in such a project. We appeal to our brethren of the press to give it their generous consideration, and their powerful aid in publicity and advocacy. We do not attempt to point out the way in which the organization should be effected, or even at present to make a suggestion. We simply ask attention to the importance of the subject.

There is another incidental and collateral advantage, which will follow upon the formation of an organization for such a purpose. There will be common ground and centre of action for photographers, with unity of sentiment, which does not at this moment exist. There will be opportunities, or rather occasions, of meeting together, in a mode involving even more common sympathy, perhaps, than in existing photographic societies' meetings: there will be the anniversaries, and that annual dinner, without which no great work in England is said ever to be accomplished. This is, perhaps, a small thing to refer to in connection with such a subject; but such meetings are not without their significance and value. To the major question, however, we earnestly ask the attention of all classes of photographers, especially of those whose position, ability, wealth, and influence can at once give to such a movement success.

THE MANAGEMENT OF THE NITRATE BATH. CORRECTING DISORDERED BATHS.

In a recent article* on the management of the nitrate of silver bath, we dwelt chiefly, as a matter of primary importance, on the most approved methods of keeping a

* See p. 385.

hard-worked bath in good order. Second only in importance to this, are the methods of restoring the working condition of a disordered bath. To appreciate these properly, it will be first necessary briefly to examine the causes which operate in disturbing the desired action of the silver solution.

A hard worked bath is apt to get out of order in a short time, from the same causes which deteriorate a moderately worked bath in a longer time; but many operators are apt to forget the hard work, and wonder that the bath gets out of order in such a short time. Besides the well known causes of deterioration, various doubtful causes are often suggested. The use of bromo-iodized collodion is a favourite cause on which to place the blame with many excellent photographers, who have had long and successful experience with iodized collodion. We do not see any theoretical reason for this supposition, and we have never found any bad results in practice, to believe that it deteriorates the nitrate bath in any respect. A very able photographer called our attention recently to a very curious experiment. A nitrate bath, in which he had been testing several samples of commercial collodion, refused to work, giving foggy, unsatisfactory results. Thinking that it possibly arose from impoverishment of the bath, he added some crystals of nitrate of silver, upon which immediately ensued a precipitate in powder of a bright yellow colour like sulphur. This experiment he repeated in our presence. We have not had opportunity of further examining the bath or the precipitate, or inquiring into the details of its history. Our friend, an able photographer, had come to the conclusion that it was bromide of silver, the precipitate answering to many of the characteristics bromide attributes to that substance. We took exception to that conclusion, because it did not answer to the qualities we have found in bromide of silver, which we have always found to be of a much lighter tint, rather resembling a light cream colour than yellow, and we believe it to be soluble in a strong solution of nitrate of silver, rather than in a weak one, as this substance was. We mention the circumstance here, in order to ascertain if any of our readers have at any time met with a similar precipitate.

The use of impure methylated solvents in the collodion may doubtless be at times chargeable as injurious to the nitrate bath. But it is to *impurity* we believe the injury is due. We believe that methylated ether and methylated spirit of good quality have no injurious effect in collodion, and we say this after considerably extended experience in their use*. If the methylated ether be good, and the spirit have been especially rectified, no evil will arise from its employment in collodion. The injurious results arose from the use of methylated spirit containing a variety of essential oils and other contaminations, which soon react upon the nitrate of silver bath in an injurious manner, and hence the evil which has been attributed indiscriminately to the presence of methylated compounds. Whether the solvents be methylated or not, there is every reason to believe that the presence in the collodion of fusel oil and various essential oils is injurious to the nitrate bath.

The use of impure iodides may occasionally be injurious; but we do not think that this is a common evil. Empirical compounds may occasionally be used for improving collodion, and these may occasionally, by accumulating in the bath, become injurious; but we do not think that this is a frequent evil. Nitrate of silver may not infrequently be contaminated with impurity, but we believe that designed adulterations are rare.

Without adverting further to hypothetical sources of derangement with nitrate bath, we will glance briefly at some of the known defects, with their causes and remedies.

Streaks in the direction of the dip and fog often proceed from the same cause—either alkalinity of the bath, or the

presence of organic matter. If the addition of a little nitric acid do not remove the evil, the bath may be sunned. Sometimes the streaks arise from the accumulation of ether and alcohol, which seem to exercise a slightly solvent effect on the film of iodide of silver formed, and produce the streaks in the direction in which the plate moves. Evaporation by exposure in an open vessel, and gentle heat, or boiling down, is the remedy. Sometimes the presence of scum on the surface of the solution will produce streaks. Drawing a strip of paper across the surface of the solution most effectually removes such scum. Streaks will often be observed immediately after strengthening a bath with fresh silver or strong solution, and will disappear after working a few plates. The fresh solution, not being iodized, exercises a slight solvent action on the iodide of silver formed; and of course that action is shown in the direction in which the plate moves. The remedy is leaving a coated plate in the bath a short time.

Pinholes and Spots.—These are amongst the most annoying troubles to which the photographer is subject, and the causes are so numerous that they are not always easy to detect. The pinholes with tails to them may almost always be remedied by the use of a larger proportion of bromide in the collodion; but the small round holes, which seem most plentiful in the dense parts of the picture, are more difficult to deal with. Dust, either in the bath or camera, is a cause too obvious to be mentioned. Supersaturation with acetate of silver is an occasional cause, and one difficult to remedy; continued exposure of the bath to strong sunlight is a partial remedy. The presence of oxalate of silver in the bath, arising from the use of old and partially decomposed collodion, is an occasional cause. When this is the case, the bath may be seen to be slightly turbid, and after standing a few hours a precipitate will fall, and the bath will again give clean plates. The best remedy is to avoid the cause. The most common cause of pinholes is the well known accumulation of iodo-nitrate of silver in the bath from long use. The best remedy is to dilute the bath with an equal bulk of distilled water, which will cause a precipitate, which, being filtered out, the proper amount of nitrate of silver is added to make up the strength. There are probably some other causes not well understood. It is noticeable that these spots will often be troublesome in warm weather, and disappear in cold weather. They will sometimes appear chiefly in a bath with much accumulated alcohol, and disappear after evaporation. Rest will sometimes cure a bath; sunning frequently, and boiling down occasionally.

A singular and empirical remedy for the many troubles of the bath is found by some operators very efficacious in removing a cloud of evils afflicting the nitrate bath. It consists in the addition of a little pure cyanide of potassium in solution. The result which might be expected would be simply the precipitation of cyanide of silver, and the formation in the bath of nitrate of potash. But something more than this seems to take place; needle-like crystals, which were seen floating in the bath and clinging to the dipper, are dissolved, and impurities are carried down by the precipitate. Whatever may be the action, the result is often very beneficial.

Want, or Excess of Density.—Want of density, when caused by the nitrate bath, is generally accompanied by fog. It may be caused by excess of nitric acid; neutralizing is then the remedy. It may be from the formation in an old bath of acetic ether; carbonate of soda and sunning are the best remedies. It may be from impurities in the nitrate; for which neutralizing must be followed by sunning. The addition of a little acetate of silver will often add to density, but we don't like the remedy. Excess of density is often due to the presence of acetate of silver, or the accumulation of organic matter; sunning is a good remedy.

Neutralizing an Acid Bath.—The use of oxide of silver, which is theoretically the best method, is not always practically the most efficient. If it be used, it should be freshly precipitated by adding a little of a solution of caustic

* It has been recently suggested by a contemporary that the injurious effect of the methylated spirits in collodion is chiefly found with pyrogallic development. Our own experience is chiefly with iron development, but we occasionally use pyrogallic acid with the same collodion and bath, without perceiving any ill effect with either wet or dry plates.

potash to a solution of nitrate of silver. The brown precipitate, having been washed in two or three waters, is then added to the bath until it is decidedly turbid, the solution well agitated and left for a few hours before filtering. The addition of carbonate of soda, besides neutralizing the bath produces another good effect; it throws down a precipitate which often takes with it other impurities present. A ten-grain solution of bi-carbonate of soda should be kept ready and added a few drops at a time until a permanent turbidity or precipitate is formed, which is not redissolved on agitation.

Adding Acid to an Alkaline or Neutral Bath.—The addition of acetic acid to a bath is a source of frequent derangement, and when once added it is difficult to eliminate. For these reasons it is better to avoid its use as much as possible. Dilute nitric acid is the most convenient for use. A drachm of strong nitric acid in 4 ounces of distilled water is convenient for use, half a drachm of the dilute acid containing a fraction over a minim of strong acid. By the use of such a preparation acid can be conveniently added in infinitesimal proportions. After each addition of acid the bath should be well stirred or agitated, and left to stand some time, as if tried immediately after the addition, its full effect will not be perceptible.

Sunning a Bath.—The bath should generally be neutralized before sunning. If it can be done conveniently, it is best exposed in an open vessel, which permits evaporation at the same time. Where this is not convenient without danger to the solution, it may be exposed in a bottle: several hours' action of strong sunlight is desirable. The solution should be then filtered, and tried before adding acid, as it will frequently be found that, after neutralizing with carbonate of soda, and sunning, a bath will work well without any addition of acid.

Evaporation and boiling down.—The partial evaporation of excess of ether and alcohol may be effected by placing the solution, for some hours, in an open vessel, in a warm place, or over a water bath or sand bath, at a very low temperature. In order to effect the entire removal of all traces of spirit, or to remove acetic acid, it is necessary to boil down the solution to dryness. Many American photographers rely on partial boiling down, as the best mode of removing almost all the ills a bath is heir to. The operation is one requiring great care. It may be effected in various ways. If partial boiling down only is intended, the solution may be placed in a well annealed flask, and supported in a retort stand; a spirit lamp with wire-gauze burner is then placed underneath, not too close at first. If boiling down to dryness be intended, the solution should be placed in an open glass dish, or evaporating basin, and placed over a water bath, the heat being raised gradually. A method may be improvised by placing the solution in the most convenient glass vessel which will stand in an ordinary open cooking vessel. The glass vessel must not stand on the bottom of the pan, but be supported by some means—if it rest on a piece of tile, it will do. The heat must be raised gradually. Frequent stirring will assist evaporation, and prevent "bumping." Well annealed vessels should always be used.

Preparing pure Nitrate from Old Baths.—One of the drawbacks of the various methods of correcting a disordered bath rests in the fact that they are often very liable to rapid deterioration again, and it finally happens that the bath has got into a state of hopeless imperfection. The remedy is then to precipitate it entirely, and reconvert it into nitrate. There are various modes of doing this; we will mention two or three. The first is strongly recommended by Mr. Gage, a skilful American photographer. Place 30 ounces of solution in a Winchester quart bottle, and add bicarbonate of soda, a little at a time, until the whole of the silver is precipitated as a carbonate, stir or shake the solution now and then. Take care that all the silver is precipitated; a little excess of soda will do no harm. Now pour off the water closely, without letting any of the precipitate escape. Re-

peat this six or eight times, so as to be sure of washing off all the free nitrate of soda.

Distilled water should be used for the last washing. After having drained it as closely as possible, proceed to add pure nitric acid, to dissolve the precipitate, stirring with the glass rod at the same time; continue to add until the precipitate is nearly, *but not quite, all dissolved.*

The solution at this point of the proceedings will probably be opaque and almost inky black. This need not cause any alarm, as it will filter out clean and pure. Now add distilled water to make up the bath to the original bulk. For certainty, it may be as well to test the strength, either with the hydrometer or by the volumetric process. Filter two or three times thoroughly, and it is ready for use. Mr. Gage says:—"Baths for negatives treated in this way work decidedly clearer, better, and quicker than in any way I have ever tried. It also gives better delineations in positives. The experimenter, by this method, will be astonished at the amount of black or green matter that will be found in the funnel after filtering the first time, and will be able to see what fogged his pictures." He adds:—

There are some points of importance to be attended to in this process. They are these:—

1st. That the bicarbonate of soda be pure.

2nd. That the resulting precipitate be well washed, to free it from all soda that is not all absorbed and combined with the silver.

3rd. That the precipitate be *not all dissolved* before it is filtered. If this part is not attended to, you will lose your labour. The theory of this is, that the *organic matter* in the bath is *soluble in acid* and cannot be filtered out while the bath is acid. There need be but very little precipitate left in, as the least amount undissolved will leave the bath perfectly neutral.

Another method consists in first reducing the bath as a chloride by the addition of common salt, and then washing the chloride several times. Then place amongst it some clean wrought-iron nails, and a little dilute sulphuric acid, say one ounce of acid in four ounces of water for each four ounces of chloride. In about 24 hours the whole of the silver will be found reduced into a grey metallic powder. Wash this with weak sulphuric acid, then with several changes of water until every trace of acid is removed. Next redissolve in dilute nitric acid; the result will be very pure nitrate of silver. There are other modes of effecting this, but these will suffice.

We have now given a brief *resumé* of the chief modes of correcting a nitrate bath; all of them are perhaps pretty well known, but our object has been to collect and condense them for general reference.

Scientific Gossip.

CONSIDERING the vast number of organic substances being every day brought to light by the labours of chemists, it is somewhat surprising that so few of these bodies have been made available for utilitarian purposes. Amongst the thousands and tens of thousands of new ammonias and organic bases which have been discovered of late years, scarcely one has given signs of possessing the least interest outside the charmed circle of chemists, which meet on alternate Thursdays at Burlington House. In one of his early memoirs, Dr. Hofmann referred apologetically to the swarms of new ammonias, of which he was the prolific parent, by comparing them to paving stones—of great use in constructing a firm path for future use, but of no individual interest when once obtained and their position and composition settled. But to some of these bodies we can hardly accord so useful a position as a paving stone. With their mode of atomic arrangement unknown, their proper position in respect to surrounding bodies unsettled, and their behaviour under the various forces to which they can be subjected, they may be better likened to crude and ill-shapen blocks of ore, hewn

by the workman from the rock, and scattered at random for others to utilise.

Foremost amongst the vigorous miners in organic chemistry stands Dr. Frankland. Scarcely a month passes without chemists being gratified by some new result, which this talented professor has elaborated with no less skill than penetration. His discoveries, especially in relation to organo-metallic bodies, are always of interest; and his latest research promises to be of some practical importance, besides being of scientific value.

By allowing iodide of methyl to act upon sodium amalgam, in the presence of a little acetic ether, a compound is obtained called mercuric methyl. This, after purification, is obtained in the form of a colourless, highly refracting liquid, of the specific gravity 3.069, being in fact the heaviest known liquid, with the exception of mercury itself. So dense is it that a piece of heavy lead glass will float upon it. The author states that in the event of this organo-mercuric compound being required in quantity, no difficulty would be experienced, as iron vessels could be used, and the process could be conducted continuously; thus syphon tubes could be made to draw off the residual mercury, and the products themselves, whilst fresh materials could be supplied by injection. Upon seeing the specimen of mercuric methyl handed round at the last meeting of the Chemical Society, the idea occurred to an ingenious correspondent of the *Chemical News* to apply this liquid to the manufacture of prisms. At present, the only liquid suitable for this purpose is bisulphide of carbon, which is not above half the density, besides being objectionable from its offensive odour, its great volatility, and the ease with which it ignites. The mercuric methyl appears to be superior to bisulphide of carbon in all these respects; and as its preparation in quantity would be attended with no particular difficulties or expense, we hope that some enterprising instrument maker will not be long in adopting this very valuable suggestion. Besides its use for prisms, this liquid might be advantageously employed in the manufacture of lenses. Formerly, compound lenses, in which one of the constituents was a fluid held between outer meniscus lenses, were somewhat in vogue, but were abandoned owing to the advantages of their construction not being sufficiently great to counterbalance the difficulties.

The well-known French chemist, Chevreul, who has devoted so much attention to the subject of colour, has lately published a memoir on painted windows, in which there are many points which deserve the attention of artists and others who are interested in the manufacture of coloured glass. It has often been noticed that old stained glass windows have a much richer effect than modern ones, and M. Chevreul, speaking of this superiority, attributes it to what we moderns regard as defects. In the first place, much of the ancient glass is of unequal thickness, or, in other words, the two surfaces are not parallel, and so present convex and concave parts, which refract the light differently, and produce an agreeable effect. In the next place, the old coloured glass is not a colourless glass, to which has been added the particular colouring material, such as protoxide of cobalt, &c. Old glass contains a good deal of oxide of iron, which colours it green, and to this must be attributed the peculiar effects of antique glass coloured by cobalt and manganese. M. Chevreul appears to think that modern stained glass is too transparent to produce the best effects. M. Regnault, another admirer of the "dim religious light," has recommended that all this kind of stained glass should be cast, to avoid the monotonous effect of plain surfaces on the light; and also that foreign substances should be mixed with the glass to diminish its transparency.

The formation of gun cotton from ordinary cotton is well known to our readers; the change consists in the substitution of two or more equivalents of nitrous acid, NO_2 , for the same number of equivalents of hydrogen. The same change may be produced in many other organic bodies; for instance, glycerine, when treated with a mixture of nitric and sulphuric acids, becomes converted into a nitro-glycerine or

glonoine, an oily liquid having explosive properties when heated. Many experiments have been tried with this substance, respecting the remarkable action which it exerts upon the animal economy, the glonoine being administered by dropping it, or its alcoholic solution, upon the tongue. The principal effect which has been noticed is the production of violent headache, accompanied by great prostration of the system. Mr. T. M. Merrick has recently had the courage to try some experiments upon himself, and, considering the violent toxic properties of this curious substance, and the peculiar manner in which it acts, the experiments are doubtless more interesting to the reader than to the experimenter. The first experiment was an accidental one; a dish containing a solution of glonoine in ether was, by some mishap, tipped over, spilling half its contents on the sand bath, and, in a moment, the room was full of the mixed vapour of glonoine and ether. A large volume of the mixed vapour was inhaled. No immediate bad result followed, but in less than fifteen minutes a headache set in, slight at first, but increasing in intensity by degrees, until, in an hour and a half, it became almost intolerable. It was accompanied by a good deal of faintness and exhaustion, intolerance of light, and a feeling of great general distress and alarm; consciousness, however, not being lost for an instant. The unpleasant symptoms did not disappear for three or four days. After this experience of the powerful action of the liquid, Mr. Merrick was a bold man to deliberately lay himself out for a repetition of the effects; but there is no knowing what an enthusiast will do in the cause of science. Wishing to ascertain what would be the effect of swallowing a minute quantity of glonoine, he prepared a solution containing two and a half drops to ninety-seven and a half of alcohol. One drop of this liquid, containing the fortieth of a drop of glonoine, was swallowed on a piece of loaf sugar. In two minutes the pulse had risen considerably, with a dull throbbing headache. In five minutes the pulse had risen higher, the headache changing from the back to the front of the head. In fourteen minutes the pulse had sunk again to its normal rate, although the pain in the head did not pass off for fifteen minutes more. This experiment shows that glonoine is a body which rivals in intensity the strongest organic poisons; it proves the necessity there is for extreme caution in handling, and especially inhaling or tasting substances the nature of which is not thoroughly well known. In inexperienced hands, glonoine may be a poison of the most mischievous character; although when employed by skilled physicians, it will, no doubt, prove a valuable physiological agent.

Messrs. Deville and Troost have lately discovered a curious property of platinum. In some experiments upon high temperatures, they were induced to suspect that the platinum vessels employed were somewhat porous to gases. They accordingly tried a definite experiment, with the object of ascertaining this. A platinum tube was placed inside a porcelain one; through the former a current of atmospheric air was passed, whilst hydrogen circulated through the latter. The pipe and delivery tubes were so arranged that the gases could not mix, but passed through and were collected apart, being separated by a solid and continuous partition of well worked platinum. At the ordinary temperature the hydrogen passes along and may be collected at the other end in the pure state, whilst the air retains its normal composition. When the temperature is raised, however, to a red heat, a change occurs, the platinum at this temperature is porous to the hydrogen, which accordingly passes through the metal, and unites with the oxygen of the atmosphere, forming water, which may be collected and weighed in appropriate apparatus. It has been proved further that the porosity increases with the elevation of temperature: at the highest point tried (about $1,100^\circ \text{C.}$) the whole of the atmospheric oxygen unites with the hydrogen, and nothing passes out at the other extremity of the apparatus but nitrogen and aqueous vapour.

THE DISCOVERER OF THE USE OF BROMINE IN PHOTOGRAPHY.

A FEW FACTS AND AN APPEAL.

BY JABEZ HUGHES.

As the early history of photography is now engaging attention, a statement of the claims of a little-known discoverer will not be out of place.

To John Frederick Goddard we are indebted for the first discovery and publication of the use of bromine in photography. The interesting circumstances attendant afford an opportunity of recording some facts connected with early photography as illustrated in the Daguerreotype process.

Daguerre, after many years of experimental labour, announced his discovery, in January, 1839, and showed specimen pictures; but it was not till August in the same year he disclosed the process itself, the French Government having in the interval purchased the secret, "as an invention that did not admit of being patented," and they generously published it "for the glory of endowing the world of science and art with one of the most wonderful discoveries of our native land." Nevertheless, Daguerre, while negotiating with the French Government, secured a patent in England.

Daguerre made few improvements; in his hands the process was only able to delineate still life objects, for an exposure of twenty minutes or half an hour, with bright sunshine, was required. Enterprising individuals, however, immediately practised the art, and went forth armed with this new power to depict celebrated monuments and other objects. Many of these thin, filmy, shimmering pictures were exhibited in London, and offered for sale at the Polytechnic Institution. They were taken on plates $8\frac{1}{2}$ by $6\frac{1}{2}$ inches, and, though wondrously admired as curiosities, found few purchasers. The prices ranged from one guinea and a half to two or three guineas each.

Up to this point Daguerre's discovery remained as a scientific wonder, but with little commercial value. Improvements were required so that impressions could be taken quickly, and in a subdued light; and these improvements were first made by Mr. Goddard.

The circumstances of his introduction to photography are curious. When the particulars of Daguerre's process were published, Professor Morse resided in Paris. He communicated the details to the scientific men of New York, many of whom immediately commenced experiments, and, among others, Messrs. John Johnson and A. Woolcott, who worked together. Mr. Woolcott, with a view to take pictures quicker, devised a camera with a concave mirror, instead of a lens, and the plate was placed in the focus of the mirror. By this means they were able, so early as October, 1839, to take a profile portrait of Mr. Johnson, with only *five minutes'* exposure in the bright sunshine, the plate being not quite three-eighths of an inch square. In January, 1840, Messrs. Johnson and Woolcott were so far satisfied with the improvements they had made in the reflecting camera (they were able to take portraits $2\frac{1}{2}$ inches by 2), as "to entertain serious thoughts of making a business of taking likenesses from life." Early in February, 1840, Mr. Johnson, sen., came to Europe with a few of the likenesses, with the intention of patenting the reflecting camera.

Mr. Carpmael, the patent agent, being engaged with Mr. Beard on patent business, called Mr. B's attention to this subject as likely to be a good speculation, and Mr. Beard united with Mr. Johnson in taking out letters patent for the reflecting camera. This was Mr. Beard's first introduction to photography. As neither Mr. Beard nor Mr. Johnson were men of science, but engaged in commerce, they felt it necessary to secure a competent person to bring out their new camera. They applied to Mr. Longbatham, of the Polytechnic Institution to name a gentleman likely to aid them. He mentioned Mr. Goddard, then engaged as lecturer on optics and natural philosophy at the Adelaide Gallery, as a gentleman exactly suited for them, if they could secure his services. Mr. Goddard, who was already familiar with the Daguerreotype process, entered into the project with zeal, engaging himself to undertake experiments to test the value of the new instrument, and also to endeavour to improve the process itself. This was about Midsummer, 1840, and although Daguerre's discovery had been about a year before the public, excepting this reflecting camera, no improvement whatever had been made.

Mr. Goddard soon found that, as all his pictures required continuous sunshine, even with his "quick-acting" camera—to use a modern phrase—he was often obliged to suspend his experiments for want of light (his premises were in Holborn), so he set to work to find a means to take pictures without direct sunshine. In the Autumn of 1840 he discovered the extreme sensitiveness of the use of bromine with iodine, a discovery which reduced the exposure from minutes to seconds, and permitted pictures to be produced in a subdued light. This valuable discovery was published in the *Literary Gazette*, December 12th, 1840. Mr. Goddard saw at once the value of his discovery in a commercial sense, and recommended Mr. Beard to purchase the patent from Daguerre, in whose hands it still remained; and also to abandon his reflecting camera as no longer necessary, but to use lenses by which larger and better pictures could be obtained. Mr. Beard had the wisdom to avail himself of these suggestions, and from this time dates the commencement of a new industrial art—professional and commercial photography.

After this, Mr. Goddard instituted an elaborate series of experiments on the haloid bodies. Iodine, bromine, chlorine, and fluorine, and in Feb., 1841, he deposited a paper in the Archives of the Royal Society, detailing his sensitive process of chlorine with iodine for taking portraits from life. A copy of this paper was presented to each of the licensees of Mr. Beard, as directions for making their sensitive solutions.

With the exception of M. Fizeau's method of gilding the plate, no vital discovery was ever afterwards made in daguerreotype, all other improvements were but matters of detail.

The introduction of bromine into photography enabled it to pass from a curiosity of the laboratory to be one of the proudest discoveries of the nineteenth century. It became immediately a new and unique source of happiness to mankind—a boon and a blessing to all brought within its influence. Due honour has been rendered to the great primo movers—Daguerre, Fox Talbot, Archer—but the claims of one still living amongst us, who found the art at a dead-lock, and who gave it an impetus which it has never lost, are not so well known. They have never been so fully stated as in this paper, and, perhaps, would not have been so urgently made now, but that the worst part of my story has yet to be told—this worthy man is in want! He is old and frail; he has well-nigh reached the Psalmist's "threescore and ten;" and he is in penury—literally without means—and is living on charity.

It is proposed to raise a fund to relieve the necessities of this deserving gentleman; and I appeal to all photographers to honour themselves and their craft by rendering the few remaining years of this early father in photography free from at least the anxieties of physical want.

Mr. Goddard has spent the greater part of his life in scientific pursuits. In the Society of Arts Session, 1837-8, he received the silver medal from the society for his apparatus for experiments on polarised light, and at the same session he contributed a paper explaining the subject. He was one of the earliest lecturers on the oxyhydrogen microscope, and was engaged lecturer at the Adelaide Gallery and the Polytechnic Institutions on optics and kindred subjects. He brought out the opaque microscope, that marvellous instrument, that exhibited a highly magnified drop of water, with its myriads of horrible inhabitants. He was the first to exhibit a highly magnified photographic image on the screen of a lecture room, the subject being a Daguerreotype of the late Prince Consort, in the presence of the Prince himself.

Fifteen years ago, Mr. Claudet, in the *Philosophical Journal*, when discussing the priority of discovery of the use of bromine, frankly conceded the honour to Mr. Goddard, and used these words:—"The name of Mr. Goddard should be honourably mentioned in the history of the progress of photography; not only for the discovery to which I have just alluded, but also for having been one of the first in England who investigated with zeal, enthusiasm, and scientific ability, the phenomena connected with this admirable invention."

I leave the matter now in the hands of the photographic public, confident that I have but to make the appeal to those who have profited by the practice of the art, to give from their stores to solace the declining years of one who helped the art when it much needed it.

To give effect to this appeal, the gentlemen whose names are appended will thankfully receive contributions, and their names will be a guarantee for the accuracy of the statements made, and for the proper application of the funds.

All monies collected will be duly acknowledged in the Journals.

Dr. DIAMOND, Twickenham House, Twickenham.

THE USE OF RESIN, &c., FOR THE REDUCTION OF CHLORIDE OF SILVER.

BY F. W. HART.

IN the process of reducing silver for testing purposes, recommended for use with my Volumetric Apparatus, the chloride is reduced by nascent hydrogen formed in the decomposition of water, the zinc or iron being oxidized (at the expense of the water) before the sulphuric acid can dissolve it; by this means the other element composing the atoms of water is liberated, and then immediately combines with the chlorine of the silver salt, which is split up, leaving metallic silver.

Most reductions from solutions, except in the case of electro depositions, are pulverulent, and require an after application of intense heat to bring the particles into a solid mass. This fact renders desirable a method of reduction which does not involve two operations. Discarding the common methods, I adopt a plan similar in principle to that I have just explained. In the method I am about to describe, hydrogen still performs the function of a reducing agent, but the final result is pure, bright, and solid silver.

It is well known that most substances burning readily contain a large proportion of hydrogen, such are naphtha (liquid), paraffin (solid), asphaltum (solid), and resin from turpentine. The two latter will suit our purpose best, being easily reduced to powder. Proceed as follows:—

1st. Let the chloride of silver be well washed, by pouring on successive changes of water, to rid it of soluble matters; then pour on a filter to drain, and, finally, well dry and powder fine.

2nd. Take two ounces of this fine powder, and one ounce of finely powdered asphaltum or resin, mix them intimately; passing through a tolerably fine sieve twice does the work well.

3rd. Have ready a good smooth assay melting crucible,* which may be filled nearly full, as there is no boiling over to be feared, as, with the ordinary processes at first, apply a gradual heat. A portion of the decomposed hydrocarbon not taken up or in excess of the chloride will burn on the top, so no fear may be entertained from its appearance. It may now be placed in the most intense part of the fire, and about two drachms of powdered calcined borax is then sprinkled on the mass. When it has lost the appearance of powder, press the mass down round the sides with a stick of wood, consolidate the fire (of coke), in which the crucible must be immersed to the top, on which place a large piece of hard coke and keep at a white heat, from ten to fifteen minutes, when you may expect the operation to be completed. The silver will be found in a button on breaking the crucible, when cold, or it can be poured out and the crucible preserved for another operation.

In conclusion, a few words on the management of the fire and stove in ordinary use best suited for the purpose may be acceptable. The coke should be chosen of a medium density. Do not use the soft, black kind. Break it in pieces about the size of a hen's egg. Before placing the crucible finally, have the grate three or four inches deep, of a good, solid, bright fire; then pack round the crucible, closely, smaller pieces of coke, bed up to the mouth, and cover, as before mentioned, with a good piece of coke. Keep the grate clear from the bottom, removing the ashes by gently raking now and then, that the current of air may not be impeded.

Of stoves, the round, close wrought-iron ones are first to

* Should any difficulty be experienced in procuring good, smooth crucibles in the country, Mr. F. W. Hart informs us that he will be happy to supply them to provincial photographers.

be chosen, as in them sufficient heat can generally be obtained to melt 3 or 4 ounces, without the aid of blowing. In the small American Queen Stove, now much used in photographic rooms, can be melted between 2 and 3 ounces by gentle application of blowing—the top doors slid close. If an ordinary fire-place be used, choose one where the fire is at least eight inches in any direction.

[Mr. Hart, at our request, made an experiment, for the purpose of testing the completeness of the return of silver obtained by this method. A small sample of chloride was carefully analyzed by means of his Volumetric Apparatus, and found to contain a per centage of 60% of metallic silver. Of the same sample of chloride, 45 grammes were then taken, and reduced as above described, and gave a button of pure silver weighing 60 per cent. of the original amount of chloride, besides a few small beads adhering to the crucible. This was effected by exposure for about a quarter of an hour to the heat of a small furnace, without artificial draught.—Ed.]

ON THE STRENGTHENING OF COLLODION NEGATIVES.

BY M. MC A. GAUDIN.

IT is the opinion of most chemists that negatives on collodion are formed of particles of reduced silver in a state of infinite division, which are lodged in a network, or kind of spongy body, formed of collodion rendered insoluble. It is quite certain that every particle of the silver formed by the reducing agents is external on the substance of the collodion, for unless it were so, it could not be formed; and it is evident, that in a picture on collodion there are two superimposed layers; the one below, composed almost entirely of spongy collodion, and the other uppermost, composed at first of iodide of silver, then, after fixing and washing, of a seed plot of reduced silver, which insinuates itself, as it were, in the interstices of the subjacent collodion.

This reduced silver possesses peculiar properties, due, doubtless, to the particles of iodide of silver unattacked by light with which it is united, before the fixing in hyposulphite has caused it to disappear. Whatever it may be, it is certain that in presence of the energetic reducing agents which have produced it, and which are renewed, pyrogallic acid, sulphate of iron, &c., this silver, I repeat, augments its bulk regularly over the entire surface of the picture, and causes the intensifying which is successfully practised now-a-days, whenever the first development does not produce the desired intensity in a picture. Even after fixing, certain salts of iron increase the mass of silver indefinitely, such as, for example, the proto-nitrate of iron, under certain conditions.

I have, for a long time, thought of obtaining intensifying by means of electricity, perceiving in it a means of arriving also at an indefinite increase of the silver already deposited. I made the attempt on several occasions without attaining any success.

The cause of my non-success, and the means by which I succeeded, are as follows.

Forced to reflect upon this singular refusal to take silver, gold, or any other metal, easily reducible by the pile, when metallic contact is well established, in the region of the sky, for example, or the silver is so dense that, upon rubbing with a tuft of cotton this region in a proof well washed and dried, we obtain a highly reflective surface, in some respects, a silver mirror, I said to myself, this surface appears very metallic; it is also almost impervious to light, and this it is which makes it fulfil its function; it allows only a bluish tint to pass, like silver deposited in a very thin film upon glass. Nevertheless, it is not completely opaque, since, in printing, we are obliged, when wishing to obtain perfect whites, to cover this region with a coating wholly impervious to the chemical rays, such as China ink, chromate of lead, &c.; therefore there must be a reason for it, and, in fact, there is only one which is found verified by the knowledge we

have acquired of the texture of photographic proofs;—it is that the metallic body which forms the picture is *disseminated* and not *continuous*; from this, there results centres of action, which are so much the more numerous as the effect of the light has been more intense; but they never *touch* each other, except, perhaps, in an over-exposed or solarized proof.

Upon the discovery of the Daguerreotype, chemists of eminence analyzed the silver pictures, and they concluded, as I have before stated, that Daguerrian pictures were entirely formed of little *isolated* deposits; and when I took up the practice of this wonderful process, I verified this fact myself, by the microscope upon prodigiously sharp pictures obtained with a diaphragm as small as a pin-hole. So then, it is the same with proofs on collodion: the particles of reduced silver are isolated from each other, and if by chance some are in contact, there are here and there some branches starting from a centre around which they radiate. But as every proof is formed of multiplied alternations of light and shade, or what is the same thing, of regions where the silver is thinly spread, but, as a whole, always disseminated with vacant intervals reserved, however small they may be between the metallic particles: it results that the electricity of the pile cannot *circulate* from one to another, as that requires perfect *metallic contact*.

Such, in fact, is the essential condition for the electricity of ordinary piles to transmit its action to the greatest distances; the most powerful tension cannot overcome this condition, which is certainly not met in collodion proofs. But we know two different methods of producing electricity, each of which has its special attraction—static electricity and dynamic electricity: the one produced by friction, the other by chemical action; electricity of tension and electricity of quantity; electricity of induction and direct electricity. That is the latest definition of it.

To arrive at the result, we shall say that there is an electricity which is propagated only by a continuous metallic contact, and an electricity which crosses the metallic discontinuities, when its force is in proportion with the interval which makes the discontinuity. Thus the powerful battery capable of the brilliant well-known electric light can enter into operation only by the *effectual* contact of its poles; but by interposing the Ruhmkoff coil, the spark becomes apt to cross distances of 50 centimetres (20 inches) to one thousandth of a millimetre, according to the power of the battery; like the lightning, which, by means of its vast apparatus, darts its bolts, which are evolved in serpentine form, exactly like those produced by the Ruhmkoff coil. Therefore, what must be done to intensify collodion negatives by the pile? We must combine its elements with a Ruhmkoff coil, and then the electricity will not fail to produce its effect over the entire surface of the proof, as though continuity existed.

In speaking of intensifying pictures by the pile, I do not wish to say that we must substitute this new method of ordinary strengthening a picture for the usual practice; but there is a very interesting case which demands its aid. I speak of instantaneous pictures, which require only the tenth of a second's exposure for small size; and it will be a very great advantage if we can, by intensifying with the pile, operate with half the present exposure only; for it is admitted that the most fugitive proof is perfect at first, and that it arrives at the desired intensity only by a development which is really an intensifying. This is so true, that I have often obtained positive proofs upon glass with sulphate of iron, which, although scarcely visible to the ordinary eye, appear under the microscope models of ideal perfection. If I do not deceive myself, these proofs were susceptible of being strengthened by the pile, according to the method I have suggested to physicists, who have suitable apparatus at their disposal, and can bring this delicate operation to a good issue, which requires a piece of good leaf to be placed on the edge of the glass plate, so as to connect with the picture, and the application of a small piece of silver upon the gold leaf.—*La Lumière.*

CHILDREN'S PICTURES.*

I AM an amateur in photography in a small way, and read the Journal, of course. Many a difficulty have I mastered by its aid. But now help is wanted, not for me alone, but for a suffering profession. Hear the case.

Convenient to me is the thriving town of B, which boasts of three photographers. Good fellows, all of them; know a thing or two, and can take a hint or a picture in reasonable time. When in town, I always look in upon them, to chat a little on art matters, and compare our work.

A few days since I walked in friend A's pleasant rooms. A is a spruce young laddie, very civil and obliging, and always balmy as a May morning to his lady customers. I found him in his dark room, rather nervous. "Fact is, Sam, I have about a dozen babies, more or less, to take this morning;" and an occasional squall from the reception room confirmed his words. A urged me to stay a little while, and I stayed.

Baby No. 1 came in accompanied by pa, who carried the baby; ma, who did the baby talk, and a plenty of it; and two small sisters, who capered and crowed to amuse the darling. Excepting that the baby's head would not keep up any way, and that he would suck his thumb, or cried if that favour was denied him, he wasn't a bad sitter. But these trifling drawbacks consumed an hour or so, and baby was only caught at last when in the act of dropping to sleep, his head held up by hand, and the countenance decidedly puttyish. Ma was dissatisfied, but pa was in a hurry, and A strained his conscience, affirming that the picture was very good. After some vain attempts to beat down prices, the party left, making room for an interesting pair of twins, whereon I fled despairingly.

Friend B is a man of few words, and those brief, like Pat's owl, "he kapes up a dale a' thinkin." I found him trying to take a family group, consisting of a mother, a spoiled three year old boy, and a six months' baby. My friend's countenance was an artistic study, and expressed a variety of contending emotions, prominent among which I could read a desire to shake the spoiled boy, and free his mind to his mother, while a desire to get a customer was fighting hard with his honest indignation. After waiting for half an hour in vain, I left him in his dark closet preparing his ninth plate, and growling something about the malignant abuse of Herod for the slaughter of the innocents.

Friend C is a bachelor of the most straitest sect. Babies and baby talk are to him an abomination. He is in dress, movements, and conversation, a model of sedate propriety. Judge of my surprise, when, on entering his room, and peering cautiously around the screen, I beheld him shaking a child's rattle with might and main, and trying at the same time, to whistle "Pop goes the weasel," with variations. At last off went the cover, but the whistle and rattle ceased, and the baby threw back its head and bellowed; mother hush-a-byed, and C, with a look of desperate resignation, prepared another plate, and resumed his musical labours; but baby refused to attend, and, as I fancied, winked precociously out of his right eye, as if he liked to see the fun. "Can't you try something else, Mr. C," said the anxious parent, and C, after profound meditation, rushed into the closet, extemporised a drum out of a gutta percha 4-4 bath, and by energetic thumping, succeeded in fixing the infant's attention. Cautiously he uncovered, and, warned by previous experience, he redoubled his musical exertions, accompanying them with a kind of war whoop and scalp dance, which would have done credit to any of Barnum's Winnebagoes. The result, I am happy to say, was a very faint picture of a very much astonished urchin with eyes like saucers; but there was a picture, and C sat down exhausted. I offered some ironical congratulations upon his success, but he was too deeply touched. More in sorrow than in anger, he waived the subject, solemnly averring that such labours as these just re-

* *The American Journal of Photography.*

ported were wearing out his very existence, and conjuring me to write the truth above him as an epitaph—

"Died of children's pictures."

Mr. Editor, what is the remedy? Can't a law be passed that children too small, or too ill managed to be spanked into quiet, shall be excluded from operating rooms?

Failing in that, can the Indian fashion of strapping infants to boards, so as to preclude all motions except winking be made popular? Astonishing babies multiply upon us, and unless a remedy is found, worthy photographers will be cut off by untimely fate. Tell us, O Nestor of photographers, what's to be done about it?

New York, Oct. 20th.

B.

PHOTOGRAPHY IN ITS APPLICATION TO MILITARY PURPOSES.

BY JOHN SPILLER, F.C.S.*

Assistant Chemist in the War Department.

THE communication which I have the honour of submitting to your notice this evening will be found to differ somewhat from those usually presented on these occasions, in respect to the absence of novelty, either in the way of chemical processes or in manipulation. Its character is chiefly historical, and its interest will be based upon the circumstance that the applications herein referred to are special in their nature, and though not entirely new, have never, so far as I am aware, been treated of or described at any previous meeting of the Society.

It will be my endeavour to give you a short account of the photographic operations undertaken by a branch of Her Majesty's Service, with which I have the honour to be connected, *viz.*, the War Department; and to describe the origin, and trace the progress of these applications during a period of about six years. Such a narrative, which I trust will possess some features of general interest, will include the description of difficulties met and partially overcome, and will involve many considerations similar to those which present themselves in the daily experience of the professional operator, whether he be devoted to portraiture, landscape, or other well-defined branch of photographic art.

In commencing my historical sketch it is proper to mention and acknowledge the employment of the camera in the Royal Gun Factories during the years 1855 and 1856, when it was first used as a means of portraying the peculiarities of construction involved in sundry schemes for the improvement of ordnance, and the application of the system of breech loading. The late Major Vandeleur, R.A., and Mr. Mac Kinlay, then proof master, worked both the Talbotype and collodion processes, and produced results of interest and value in their Department, but which were not distributed to any extent, in consequence of the limited opportunities available for their production on the part of officers performing other duties of a more pressing nature, and of an entirely different character.

In the summer of 1857 the Officers connected with the Royal Artillery Institution, Woolwich, were desirous of introducing the study of photography, and in September of that year the committee invited me to undertake the Officers' class newly formed, and to give a course of instruction in the principles and practice of the art. The acceptance of this appointment led to the working out of new directions, or rather extended applications of photography, and the camera was frequently employed in the representation of military subjects, in the production of drill pictures, and other illustrations of suggested improvements in the form and use of artillery *matériel*.

Foremost among the officers stationed at Woolwich, who thus appreciated the value of photography, was Lieut.-Colonel W. B. Gardner, R.A., at that time Superintendent of the Royal Military Repository, and it was mainly due to the influence and exertions of this gallant officer that photography so quickly assumed the importance which it has ever since maintained in connection with the War Department. Colonel Gardner succeeded in inaugurating the appointment of photographer to the institution of which he was the head, and in that capacity I commenced service in April 1858, not, however, following this as my sole occupation, but devoting usually one day in the week to the practice of photography, my duties as Assistant Chemist in

the Royal Arsenal not permitting me to give a larger share of time and attention than that already specified. This post was retained by me during three years, at the end of which time the Secretary of State for War determined to extend greatly the operations of the photographic establishment, by appointing a military staff, and placing the entire direction in the hands of the Chemist of the War Department, under whom I continue to superintend the production and general issue of photographs. By this step of centralization, a number of independent branches became absorbed, or united into one General Photographic Establishment, *viz.*:—The Royal Military Repository, Woolwich; the several Manufacturing Departments in the Royal Arsenal; and the School of Gunnery, Shoeburyness.

It is in this place proper to remark that the Topographical Department at Southampton, under the direction of Colonel Sir Henry James, R.E., remains perfectly distinct, its objects being special, and is in no way affected by the amalgamation lately brought about in other branches of the War Office. In a similar manner the photographic establishment at Chatham, so ably superintended by Captain Schaw, R.E., has a separate maintenance and action, although the work performed does not differ widely from that undertaken at Woolwich.

Having thus briefly sketched the origin of our present establishment, it becomes necessary to say a few words about the staff, and to describe the nature of the work itself. At Shoeburyness we are favoured with the assistance of Captain H. J. Alderson, R.A., Superintendent of Experiments at the School of Gunnery, and in this aid we are particularly fortunate, since much of the work executed at that station has special reference to the new systems of attack and defence, and to the registration of the effects produced upon the armour plating, by shot and projectiles of every description. Such results are so satisfactorily recorded by means of photography, that these illustrations have been adopted in the reports presented to Parliament by the Iron Plate Committee. Captain Alderson has attached to him for this duty a staff-sergeant and gunner Royal Artillery, both of whom have received a course of instruction in photography, and now exhibit very considerable aptitude in their work.

Besides the above-mentioned, we have at Woolwich five non-commissioned officers, Royal Artillery, the majority of whom have been instructed by myself. They are engaged in printing from the negatives sent us from Shoeburyness, and from other plates illustrating gun drill, bridging, and military engineering, produced formerly by myself, and at the present time being constantly augmented by additional subjects taken in the grounds of the Royal Military Repository, by Sergeant James Inglis, R.A. An excellent series of mounted guns, store carts, ammunition and ambulance waggons, and a variety of other carriages included in the artillery field train have been photographed on a somewhat large scale by Mr. Henry Butter, Chief Draughtsman in the Royal Carriage Department. The views taken by that gentleman, upon 15 by 12 inch plates, during the progress of experiments upon the battering of the Martello Towers at Eastbourne and Box Hill, are probably inferior to none of their kind.

The character of the work performed at Woolwich has been, to a certain extent, already defined; but it will be worth while enumerating a few more instances in which photography has been usefully applied. The soldier's kit, as laid open for inspection; the uniform and accoutrements worn by different regiments; the harnessed horses composing an artillery team; mulo draughts for mountain travelling; Canadian equipment for conveying guns and military stores in a cold climate; ammunition boxes and modes of packing medicines, and small stores for transmission to distant stations; tents and marquees; camp cooking-apparatus; pontoons and gun rafts; tackle, gins, and other appliances for mounting and dismounting guns, and landing the same from boats; repairing operations shown in stages, such as the rebouching of cast-iron guns, and refacing Armstrong ordnance; burst guns, showing the lines of fracture; modes of repairing disabled gun carriages; portable fire engines; molten iron and hot shot furnaces; war rocket apparatus; construction of earth-works, traverses, rope mantlets and other means of defence; the record of damages caused by accidental explosions, &c., &c.

Some progress has been made also in the delineation of complicated machinery, particularly that used in the manufacture of the Enfield rifle, and of the bullets for the same. Difficulties have, however, been encountered, partly from the want of light in the workshops illuminated only with a northern aspect, and

* Read before the Photographic Society, on the evening of Tuesday, December 1st.

with the glass in the skylights not particularly pale; also, from the great depth of focus rendered necessary by the dimensions of the machine, and often the practical difficulty of getting a clear view, and of retiring with the camera to a sufficient distance. Some of these requirements are identical with those involved in the taking of drill pictures of considerable size; when, for instance, an artillery detachment is grouped far and near around the gun, and some are engaged in the act of loading with heavy shot, or implements in hand, which renders it difficult to remain perfectly steady for more than a few seconds. Under these circumstances, the optician will recognize a certain degree of difficulty in so accommodating the lens as to take the entire group with rapidity and tolerably uniform definition. A lens well adapted for this kind of work has been recently prepared for us by Mr. Dallmeyer. It is a single objective of four inches diameter, and about eighteen inches focus, and may be used with a one-and-a-half-inch stop. The aplanatic lens of Mr. Grubb, of Dublin, appears likewise to answer well for these purposes. In cases where a larger exposure is possible, the "triple-achromatic" of Dallmeyer has given us great satisfaction, and with this lens there is no difficulty in getting both the foreground and distance well defined.

Correspondence.

FOREIGN SCIENCE.

[FROM OUR SPECIAL CORRESPONDENT.]

Paris, December 9th, 1863.

At the last meeting of our Photographic Society, the following letter from M. Marion was read:—

I have the honour of submitting to the *Société Française de Photographie* a new process for printing positives without salts of silver or gold, the sensitive agents of which are the red prussiate of potassa and citrate of iron combined. The invention of this process is due to M. Motileff; but certain modifications we have made in the preparation of the paper render it, we believe, more sensitive. To obtain brilliancy in the albumen, we have worked in concert with M. Motileff. We place at the disposal of the members of the society present at the meeting some samples of this paper, that they may experiment on the process and afterwards give their opinion upon it.

This paper is exposed in a printing-frame under a negative for 30 or 40 minutes in the sun, and after being satisfied that the proof is sufficiently strong, it is washed in ordinary water, and the operation is concluded; the picture, which, on being removed from the printing-frame is sticky, is cleared in the washing from the veil that covers the details, and in a few minutes it acquires the brilliancy and delicacy of tint of the finest Prussian blue, with the lights perfectly pure.

To tone this blue picture a black, it is immersed in an alcoholic solution of caustic potassa, 1 part to 300 parts water. The blue proof must remain in this bath until it becomes yellow, which takes place in one or two minutes. It is then well washed in ordinary water, and then we pour on the yellow picture a small quantity of the following alcoholic solution:—

Alcohol (40°)	100 parts.
Gallic acid	8 "

In a few seconds, we perceive the yellow picture change to inky black, and acquire great vigour; it is then dried without being washed, and is thus both toned and fixed.

I believe that the toning of the blue proof to a black requires to be studied; it demands the attention of all who are engaged in photography, for it contains questions of the greatest interest. First, in the economy of production of the proof, which cannot be denied, and next, the permanency of the pictures, a more delicate question, which cannot be solved until after numerous experiments by a great number of persons, each bringing his tribute of art, knowledge and skill.

M. Leon Vidal, of Marseilles, has completed and will soon publish a work the object of which is to show how the time

of exposure in the camera may at once be ascertained, with a given focal distance, diaphragm, and definite luminous intensity. His aim is to effect an appreciation of the luminous intensity at the moment of operating, and then to calculate, on the basis of this measured intensity, the time of exposure, with a given focal distance and diaphragm.

These calculations are put into a table, giving all the mean durations of the times of exposure in hours, minutes, and seconds, for focal distance, from 1 to 100 centimetres, with diaphragm of 1 millimetre to 20 millimetres in diameter.

This photometric table is calculated on the following basis, verified experimentally:—A simple $\frac{1}{4}$ plate objective, in the best condition of light, requires one minute's exposure upon dry collodion, with a focal distance of ten centimetres ($\frac{1}{4}$ inches), and a diaphragm of 5 millimetres in diameter (one-fifth of an inch). Starting from this basis, and supported on these two laws—1st, that the intensity of light on the unit of surface varies in the inverse ratio of the square of the luminous point from impressed surface; 2nd, that the intensity of light varies in the direct ratio of the square, of the diameter of the diaphragm giving access to the light. M. Vidal has established, mathematically, the time of exposure upon dry or wet collodion, whatever the intensity of the light, always taking into account the diaphragms and local distances employed. These calculations are applicable to every kind of objective, single or double. On this subject, M. Vidal again expresses the wish that opticians and makers of apparatus would mark the focal distances of the lenses on their tubes; upon diaphragms, a number indicating their diameter (in 10ths of an inch), and on the base of the camera and its extension, the graduated metrical distance, starting from the front containing the objective. In this manner a simple inspection would always permit the operator to ascertain under what mechanical conditions he is operating.

The photometer presented by M. Vidal to the Photographic Society of Marseilles, on the 8th of October, 1862, is based upon the colour albumenized paper assumes, by the chemical decomposition of its chloride of silver. The scale of graduation is concentric with a strip of sensitive paper, of which only a portion is exposed to light through an aperture easily uncovered. The graduated scale is composed of ten tones, arranged in such manner that each increases a degree from that obtained in six seconds in the best conditions of light to that obtained in one minute or sixty seconds, so that we thus have the series of tones obtained in from six to sixty seconds. The operation consists in measuring the intensity of the light in the open air, always done in the shadow of the body of the operator, standing with his back to the sun. The duration of this operation is one minute, measured by a sand-glass. It is easy, during the operation, to bring the eye to compare the tones on the exposed paper with those which best correspond with that obtained by the chemical action of the light of the moment. The appreciation is very easy, and if error were possible, it would be only in the series of the last five tones, in which case a hesitation between two consecutive tones would cause but a very slight error, which may be overlooked. The degree of light being known, it becomes easy, table in hand, to deduce from it the time of exposure, the numbers of the table being based upon the No. 10; that is to say, upon the best conditions of light.

CHROMOPHOTOGRAPHY.

SIR,—In No. 273 of your journal, Mr. Busch has criticized unmercifully my little discovery in Chromophotography, regardless of the favourable opinion expressed by some, whose names are of note in the photographic world.*

* 1. "Phio del fotografo," by J. G. Sella, new edit., 1863, page 466:—"Il Colonnello Baratti, per colorare le prove propone l'uso di soluzioni," etc. "Le immagini così trattate quando sono rifrate nell'iposolfite, sono di grande effetto pereré la tinta e gradazione di esse, non e monotona

Has Mr. Busch thoroughly examined that process which he stigmatizes over freely, declaring that it "does certainly not look like a step in advance," and settling that I* "only substitute painting them (*the photographic images*) over with colours," which latter process, he is "afraid, is decidedly the better?" Evidently, Mr. Busch does not know that, in condemning my chromophotography, he speaks against his own interests, otherwise he would not drive the photographers to the abolition of the toning process, he who is a manufacturer of chloride of gold, if I mistake not. Hence Mr. B. ought to know very well that the solution of this salt is colourless, and therefore you cannot *paint* with it, though you may tone with it; and, as a chemist—even if he has not read the theory of toning by Messrs. Davanne and Girard, now publishing in your journal—he ought to know that the tint produced by gold is effected by substitution—"a portion of gold is deposited, a portion of silver is dissolved, and gives place to the gold." Consequently the image preserves all its original purity, while water or oil colouring, which he is afraid is decidedly the better," is a process of superposition, which covers the photograph with colouring matter extraneous to the sun printing, and debases the exquisite merit of truth, hides the delicate lines of the picture, seeks to trick you into believing it to be the wonderful effect of chemicals and light, when it is nothing but an abortion that is not worthy the name of a picture or a photograph.

If Mr. Busch is contented with this sort of hybrid production, let him enjoy a satisfaction I cannot envy him. And, in fine, as Mr. Busch modestly reserves to himself, in his quality of chemist, the privilege of solving the problem of photography in colours, excluding from such studies all us ignorant photographers. We wish him full success in his researches; and if, after a long and painful incubation, should they give birth to a little mouse, still it will be a mouse, and we will never say that "it does not look as a step in advance."—Yours,

L. COLONEL C. BARATTI.

Milan, 6th December, 1863.

Photographic Notes and Queries.

COLOURED PHOTOGRAPHS, OR DOUBLE TONING.

DEAR SIR,—I noticed in your last impression Signor Rizzo's and Colonel Baratti's dispute of priority on colouring photographs by toning process. I trust that I may be allowed to remark that the invention (as it is called in Galignani's), is not a *new discovery*, inasmuch as any one who has been familiar only for a short time with photo-toning, must surely have noticed the different hues obtained by the various degrees of toning, and fixing with or without toning, by hypo, ammonia, &c., &c. The novelty, however, might consist in the application; but this, too, is misunderstood; and at all events, of no practical use.

No doubt we may tone the face one colour, the coat of another, and so on, but it will always represent the portrait of some one afflicted with yellow or other fever. There is nothing more difficult to render truly as in nature, than the blooming complexion of a fair lady in all its delicacies of light and shades. How, then, could a manipulator, however skilful he might be, produce softness and vigour, almost on the same spot; insensible gradation and variation of tints; minute sharp touches of shade, outlines neat and true, and solve many other artistic difficulties by means of a bath or solution? Moreover, if we have to use the brush in toning, it will be far better to use it comfortably, with the aid of stick and easel, in plenty of white light, when the artist can mix, judge and alter the pigments at his own fashion and fancy, better than in the yellow or gas light. Last year I tried more than once to utilize such a method of fancy toning, but as my time is not my own, it was not until last spring that I succeeded to something worth mentioning. In the

ma, vario e conveniente. I ritratti guadagnano maggior vita quando, vengono trattati con questo metodo."

* See a letter on the same subject in the *Camera Oscura*, page 143.

3. Vid Ind., page 178, etc.

* I do not say *our*, because I alone have published the process in question, and the *Galignani* took his quotation from an article of mine in the *Camera Oscura*, and the public and myself are, as yet, ignorant of any other publication of that kind.

usual gold solution, I toned a whole-plate portrait of the Princess Alexandra, with the only difference that I made the hair of a *rich fox hue*, and the ribbon binding it behind of a *pinkish tint*. Again, a whole plate portrait of Lydia Thompson, the hair of a *decided golden colour*, and the coronet of a *rich velvety true purple*. I was pleased with it, and I named it *double toning*, from its relation, double printing, and showed those and few similar experiments to my principal, but as it was not a question of L. s. d. to him, it was there and then condemned as losing time in playful nonsense. Although my friends admired very much the pleasing contrasts of double toning, yet I could not see in it any practical use. Lately, however, I found out its application, and very beautiful it is too. If landscape views are toned gradually from very cold to very warm tones, a skilful manipulator may produce such effects that no artistic brush or crayon work can compete with. There you can obtain the true effect of sunrise and sunset; you can represent the effect of a conflagration; and many other very beautiful artistic contrasts can be managed. The enclosed I venture will give you an idea of what I mean, and although very poor, imperfect and bad proof, yet you will be able to judge that the application is true, and of the vast new field, which is opened to photo amateurs to show their artistic feeling. I shall be thankful of your opinion thereon. Apologising for trespassing on your valuable space,—I am, dear Sir, faithfully yours,

P. T. COZZO.

[The question is, will the results to be obtained be commensurate with the trouble? Doubtless the process may occasionally find useful application, and we have seen some pretty effects.—Ed.]

MEASURE OF THE ANGLE, &c.

SIR,—I have seen a good deal of correspondence lately in the PHOTOGRAPHIC NEWS concerning the angle included in various lenses. Surely there is nothing more simple than to get the correct angle of a lens with the prismatic compass, which I have always used for that purpose. I follow the simple plan of placing the prismatic compass on the top of my camera; when requiring the angle contained by the lens, I focus sharp (as near the left edge of the focussing glass as possible) some conspicuous building, such as a church. I then take the bearings of the church, or building, and then, having marked some point (probably a tree) which is perfectly sharp on the right-hand side of the ground glass, I take the bearings of that. I then deduct the number of degrees of one from the other, and the result is, I imagine, the correct angle contained by the lens.

I have used your chloride of lime toning bath with great success. I found adding a few grains of acetate of soda an improvement.—I am, sir, your obedient servant,

H. DUBERLY, Major 8th Hussars.

Simla, East Indies, October 1st, 1863.

[To obtain certainty by this method, it is necessary that the compass be in contact with the optical centre of the lens. With the triple the place of the stop is near enough.

NITRATE OF SODA IN THE PRINTING BATH.

SIR,—As a photographer, I have for a considerable time felt great interest in the discussions now going on in various photographic societies, on the strength of floating bath necessary to secure the best and most uniform results in printing. Professionals and amateurs are alike at their wit's end, by the very opposite results arrived at by different persons, using even the same formulæ; this is particularly the case in using nitrate of soda; one gets prints of unsurpassed brilliance on an 80-gr. soda, and 30 or 40 grs. silver, while another, (to wit, "Cantab," in last week's News) finds that, with the same materials, and in similar quantities, *his albumen is dissolved from the paper!* Now the experience of "Cantab" exactly corresponds with my own. Being anxious to try the soda nitrate bath, I added 30 grs. of that material to a 40-gr. bath. On floating old albumenized paper on this bath for 4 minutes, I got tolerable prints, but not equal to a 60-gr. bath with 2 minutes' floating. I then tried some new Rive paper, No. 48, when the albumen immediately dissolved off in patches, covering the surface of the bath with transparent froth. Determined not to be done, I added silver to make it up to 80 grs. nitrate silver, still the addition of soda originally made, caused the albumen to dissolve. I then added

as much nitrate of soda as made the quantity up to 80 grs. per oz., and I have never been able to get a print fit to be seen since. The albumen dissolves as before. I added as much nitric acid as yielded a faintly acid reaction, and then found the albumen to remain intact, but the colour of my prints in toning is blue, grey, green, mud, and, in fact, every variety except what a professional can send out. Now, Mr. Editor, what is this "photographer's assistant" to do? If I add nitric acid to my floating bath, it again becomes alkaline in about 60 hours, even if it is not used, and I almost come to the conclusion, that in the practice of our interesting "black art," I must have done something to secure the presence of "his sable majesty," who gratifies his propensities by turning my floating bath into an alkali establishment, or a soap manufactory.

As you have recently published "Jottings by a Photographer's Assistant," which have materially helped me into my present difficulties, you will perhaps now publish this jotting of

ANOTHER PHOTOGRAPHER'S ASSISTANT.

Walton, near Preston, Dec. 7th, 1863.

[Why the tone of our correspondent's prints should become "blue, grey, and green," when nitric acid is added to his bath, we cannot tell, as the legitimate effect of that acid is to keep the tone warm. Neither can we see how his bath should, when so made acid, become alkaline without use.—ED. P.N.]

PHOTOGRAPHY IN A GALE.

SIR.—The view from our house is admirable for artistic and photographic experiments, about fifty yards from the sea, and opposite Portsmouth and Spithead. At 1 P.M. on the 3rd, when the gale was raging at its greatest power, the wind about 65 miles an hour, I brought my No. 4 triple lens to bear upon the brilliant and boisterous scene.

I am glad to say I obtained a capital negative in fifteen seconds, No. 1 stop, on a 12×10 plate, a 40-grain bath, and Ponting's bromo-iodized collodion. Of course, the sun was shining magnificently, producing as clear and vivid an image on the focussing glass as in a summer's day.

I also tried a plate sensitized and preserved fourteen hours, by Blanchard's honey process. I obtained a good negative in three-quarters of a minute. The tone of the darkest parts, a coppery red, and of the sky, bluish green.—I am, sir, yours truly,

H. KIRWAN ROBINSON,

Capt. 5th Royal Lancashire Regt., late 4th Foot.

Clyde House, Ryde, I.W., Dec. 7. 1863.

AUTOMATIC WASHING APPARATUS.

SIR,—On reading the description of an automatic washing apparatus, by Mr. C. Hanbury, in the last number of the NEWS, I find it is identical in principle, and nearly so in construction, with one which I contrived myself about three years since, but which I have never yet put in practice on any considerable scale. As the method appears, from the description given, to answer, I am induced to mention an arrangement which formed part of my own apparatus, viz.—The addition of two rollers, made either of lignum vite, or loaded, for the purpose of giving them sufficient weight. The rollers being set in a frame which connects them together, pass over the piles of prints in the two halves of the rocking trough, alternately, each in its own division, and, by their pressure, squeeze out the solution from the pores of the paper, ready for the absorption of the next portion of water. These rollers, it will be seen, fulfil also the office of the bullets described by Mr. Hanbury, and are, in a self-acting form, intended to carry out the rolling principle of washing proposed some time ago. In my arrangement, the prints were put between sheets of thin gutta-percha, which, when released from the weight of the roller, float and allow the prints to be freely soaked again by the next supply of water. Should you consider this of any interest to your readers, it is quite at your service.—I am, dear sir, yours truly,

Dec. 8, 1863.

CHARLES W. SMART.

Talk in the Studio.

NEW PHASES OF PHOTOGRAPHY.—We observe a new method of rewarding labourers, which must be after Mr. Disraeli's own heart; it is so ostentatious and ineffectual! "Some country

magnates have conceived the idea of having a book of photographs of all the oldest workmen employed on their estates." It is quite worthy of the brilliant agriculturist intellect of the country, to work labourers like horses and then put their cartes before them as the reward of merit!—Fun.

HIGHLY COMPLIMENTARY.—A gentleman—it might have been the writer of this paragraph—felt very uncomfortable a week or so ago when, on going to sit for his photograph, he was asked by the artist, who was by no means "happy" in the pronunciation of some of his words, whether he wished to have his "fool-face" taken.—Fun.

A CURIOUS PICTURE GALLERY.—A correspondent of *Notes and Queries* writes: "In the *Critic* for Nov. 15, 1852, is the following statement: 'The *Revue Geneve* states that the Federal Council has authorized the Department of Justice and Police to incur the charge of photographing the portraits of persons breaking the laws by mendicancy in cantons where they have no settlement. It has been found that the verbal descriptions hitherto relied on are insufficient to the identification of the offenders.' What a curious picture gallery the police will ultimately form, if this system is carried out!"

"CURED" PHOTOGRAPHS.—A correspondent in the country sends us a curious specimen of photographic advertising, in the shape of a peripatetic photographer's handbill. Our correspondent would be glad to know, if any reader can inform him, what step is taken to cure photographs, as referred to in the following paragraph: "The advertiser's photographs will, he thinks, meet with the approbation of his visitors, his photographs being properly cured and varnished, and warranted to keep well. A trial will convince that Mr. T. uses none but the best Parisian apparatus, combined with a thorough knowledge of photographic chemistry, and wishes to draw attention to his coloured portraits, which are fair and lifelike, the lights and shades being developed."

WIDNALL'S MOUNTING MACHINE.—This is an exceedingly clever and ingenious invention for assisting in the rapid, exact, and neat mounting of photographs. It consists, in the first place, of a box about 10 inches by 9 inches, and 3 inches deep, containing the complete apparatus. When opened, the lid is found to be lined with a slate, upon which the starch or other adhesive material is spread, and what a printer would term, "distributed" by means of a roller, which is also used to apply the paste to the print. In the box itself is the mounting machine. Upon a frame, provided with moveable guides, the card is placed; upon a small block, just the proper size, the print is placed, face down. An ingenious system of rollers, springs, &c., are now brought into play by a touch, the result of which is that the print is held firm by four small clips, like delicate little fingers. The roller, with paste, is now passed over the print; the frame containing the card is then turned over, and falls exactly on the print in proper position. Another touch releases the clips; the frame is lifted, and the card, with the print duly attached, is removed. Rolling with a clean, dry roller, to perfect the contact and expel the air bubbles, completes the operation, which is very much shorter and simpler in practice than in description. The rapidity and neatness of the operation, and the compactness of the apparatus will recommend it to all photographers, but especially to amateurs.

IMPROVED DARK BOX.—We were recently favoured by Mr. R. H. Michell, of Cardiff, with a sight of a dark box, which contained some very excellent points. In general construction it very much resembled Mr. Blanchard's developing box, recently described in our pages, but with certain differences. One of the first consists in a mask or eye-piece fitting to the upper part of the face, fixed to the box where the usual yellow glass is, so that when the operator is at work he looks at his plate direct without yellow glass, his face effectually keeping out the light. A sliding door closes the aperture, when not in use. The glass which admits yellow light into the box at the top, is covered, whilst travelling, with a flap, which, opening back with a hinge, makes increased table room at the top when at work. The interior is so contrived by grooves and turn buttons, that, when packed, everything fits and remains in its place, and the box may be turned in any position without risk to the bottles. The complete equipment fits inside, camera, lenses, and everything; and the whole, with stand, weighs 28 lbs. The calico part of the box containing the sleeves is fitted on to a moveable frame, which is taken out at will, to work freely in the box, when darkness is not required. The box fits on to the tripod very cleverly and

simply. The tripod head is a large triangular piece of wood; at the bottom of the box is a triangular frame, exactly fitting the tripod head, on to which it slides. A strap, which forms part of the fastening of the box, is then buckled round, and holds all firm. There are several other clever little contrivances.

THE OLD PHOTOGRAPHS.—The *Birmingham Daily Post*, commenting on the evidence of the alleged photographs of the 18th century, says:—"Once more we call attention to the fact that a large collection of the papers, working models, and machinery devised by James Watt still remains in dishonourable dust at Heathfield Hall. As this important light on the history of photography has come from a mass of old papers and rubbish of the Boulton family, it is most probable that some further important details might be procured from a careful examination of the treasures still remaining at James Watt's house." It further adds:—"What further revelations this romance of photography may disclose, it would be premature to speculate; but already there seems to be ample evidence that the vaunted discovery of Daguerre and Niepce was practised in our own town more than half a century before. As this subject has so great a local interest, we intend to publish a summary of the very important documents lately published in the *Photographic News*, and in which the curious details of these remarkable discoveries are fully described.

To Correspondents.

F. G.—Members of the Photographic Society will have the first claim to space for exhibition, and will be exempt from charge. Non-members will be permitted to exhibit on payment of a small rent charge for space, &c.

NORTH, W.—The design is very good, but would be better with the glass to the ground. If you have space, the room will be better if 10 feet longer and 6 feet wider. See an article in our forthcoming ALMANAC, with several designs and much information on glass-houses. 2. So far as we know, all the samples of collodion you mention are good; perhaps we should give No. 3 the preference. 3. See remarks on pinholes in article on the management of the nitrate bath in the present number.

THOMAS LEWIS.—Mr. C. E. Elliott's address is Aldermanbury Postern. We believe you will generally find it in our advertising columns. We do not know of any inconvenience in the use of the dark box from moisture dimming the yellow glass. We have not used it ourselves, but we know that Mr. Blanchard has used it for producing many hundreds of very perfect negatives. He informed us that he recently took it out in Brighton, taking 12 clean plates with him, and returned very shortly with 12 of the best instantaneous negatives he has produced, not one plate a failure. From this we infer that the manipulating facilities of the box must be tolerably perfect. 2. So far as our experience and information go, No. 1 decidedly. Consult him as to what will best suit your purpose.

P. HENDERSON.—Various accounts of recent methods of silvering glass for reflectors have appeared in our pages; you will find one on p. 530 of the present volume. We have not heard further from the Editor of the *Electrician* on the cheap battery referred to, but will communicate with him. Mr. Busch, whose address will be found in our advertising columns, will doubtless give you the required information.

FOOTH.—The term over-intensified should generally be used instead of over-developed; the latter term had its origin at a time when the processes of development and intensifying were carried on both at the same time. It means that the intensification has been carried too far, and chalky lights in the print result. Your prints are slightly over-intensified, and consequently want detail in the lights. If you observe the forehead of each figure, especially of No. 2, they lack gradation, presenting a mass of white, without modelling. A little longer exposure, and a little less intensification, would probably have remedied that. 2. In our opinion, No. 1.

CAMERA.—As a general principle, a single lens is better for landscapes than a portrait lens, but if you are content to work with a very small stop, the portrait lens will give good results, and it is probable your quarter-plate lens will give you very good stereo pictures.

J. RAINE.—So far as we can judge from your plan, the design of the glass room is excellent, and we do not see any alteration to suggest. We do not see that a glass room at each end is necessary. See our forthcoming ALMANAC on the subject.

D. W. ABERDEEN, AND OTHERS.—Mr. T. R. Williams informs us, that since our article in a recent number describing his lighting and other studio arrangements, he has been inundated with letters asking for advice in special cases of lighting, for specimens, &c. Having already answered more letters than his convenience should have permitted, he has handed the matter over to us. We would here suggest to our readers, that when a very busy and successful portraitist permits us, for the benefit of our readers, to examine and make public every detail of his working arrangements, it is scarcely fair that he should be troubled with letters from strangers asking him to enter into their special troubles, and give special professional advice. We endeavoured to accurately describe his arrangements, and the principles upon which they are based; the application of these general principles to special cases must be made by individuals. The glass room of "D. W." is quite hopeless, as regards getting anything like similar effects of lighting. With a top light of nine feet wide it will be impossible to cover part and place the sitter so that he practically illuminated with a high side light, as in a room 30 feet wide. Your pictures have too much front light and too little side light; the conditions just require reversing; experiment alone will decide to what extent you can do that. A white screen will reflect more light than a blue one.

P. O.—You will find instructions for taking enlarged negatives in our forthcoming ALMANAC. Your pictures possess some good qualities, but will be improved by a little more care and delicacy in manipulating. Avoid under-exposure and over-intensifying, and observe the works of able men for studies of position, &c. See our ALMANAC on pinholes.

JONAS.—"Medicated spirits of wine" is a term applied to ordinary spirits of wine, with some slight addition by the chemist to justify him in selling it without a spirit licence. 2. It may be used for burning in a lamp; but methylated spirit (which, possibly, you mean) is much cheaper and quite as good for the purpose. 3. It entirely depends upon what addition has been made to it, as to whether it is suitable for photographic purposes. 4. You are guilty of piracy if you make a copy of a copyright engraving for any purpose whatever; but the risk consists chiefly in disposing of the copies. If made merely for your own use, we do not imagine that you would ever be questioned on the subject. The risk you run is that of paying legal penalties. 5. We have occasionally seen a No. 2 B lens and camera for sale, second-hand, but have no connection with such transactions. We must refer you to our advertising columns.

TYRO.—There are very many excellent elementary works on chemistry. That in "Chambers' Educational Course," price 3s., is very useful. "Galloway's First Steps in Chemistry," 5s. As a small work of reference nothing is better than "Fowne's Manual of Chemistry," 12s. 6d.

C. F.—Your bath has, probably, become weak and exhausted with use, and possibly alkaline. Use a stronger bath, and the albumen will not be dissolved.

J. C. CUSTENDALE.—The subject of alkaline development has been fully detailed in various articles in the *Photographic News*. The only mode of dealing with collodion which has tendency to leave the plate, is to use a preliminary coating. We prefer old honey for mixing with the tannin solution.

COLONEL STUART WORTLEY'S GLASS ROOM.—We have had some inquiries for details of the construction of Colonel Stuart Wortley's studio, to which we promised a reply, which the Colonel's absence from town has delayed. We shall give diagrams and description in our next.

J. H. B.—The general plan of your glass room will do, but the side lights should be longer than 4 feet. We should prefer them as long as the top light. 2. The red fog on the shadows during intensifying is not an uncommon trouble, and may arise from several causes too numerous to treat in this column. The free use of citric acid is frequently a remedy. The subject is fully treated in our ALMANAC, and also on page 361 of the NEWS, vol. vi.

ALPHA.—The design of your glass room is excellent; the only alteration we would suggest is 3 or 4 feet additional length, if convenient. You will find a long article on the subject in the forthcoming YEAR BOOK. The mode of warming much depends on circumstances. Hot water pipes are cleanest; a gas stove is also clean; a coke stove next, and, least clean, any kind of stove or fireplace in which coal is burnt.

AN AMATEUR, Lancashire.—We have had no experience with the lens in question.

SODIUM.—Add the carbonate of soda, drop by drop, towards the end of the reaction, and notice if a precipitate is formed after each addition. Where no more turbidity is produced, add a few drops extra, and boil. Filter, and finally purify the iodide of sodium by crystallization. We believe you may obtain it of Hopkin and Williams, and probably of various other manufacturers of photographic chemicals.

J. GILBERT.—We do not know the address of any manufacturer of protosulphate of iron, but that of Mr. Barnes, of Walker, near Newcastle, at whose establishment it was stated, at the last meeting of the British Association, 2,000 tons are manufactured annually. 2. Almost all manufacturers of photographic chemicals prepare iodide and bromide of ammonium, but we cannot tell you the largest maker.

C. W. G.—We shall be at the office on Thursday, any time after 2 P.M. The three first days of the week, we are generally at our residence, 18, Canouber Park South, N.

W. D. B.—We do not know of any patent you will infringe by taking photographs on opal glass. To get transparencies on such glass to look well by reflected light, it is very important not to over-expose them, to use plenty of citric acid in the developer, and then to tone them by some method. Chloride of gold may be used, or bichloride of mercury, followed by a very dilute solution of ammonia. They may be produced by the wet process, following the method employed for lantern slides. Mr. Blanchard describes his method in our forthcoming ALMANAC. 2. In the formula to which you refer, there is, we think, too much chloride of lime; from one to two grains to each grain of chloride of gold are generally sufficient. We should be glad to hear of your formula.

ALPHA.—The tones of your prints are not such pure blacks as we see obtained with the lime bath. We do not apprehend that your bath will keep after the addition of carbonate of soda. It is not perfectly safe nor desirable to neglect washing before toning.

Several Correspondents in our next.

A HINT ON DOUBLE PRINTING.

THE methods of obtaining various effects by two or more printings on one picture have become very popular, and are largely practised. A vignettted image merging into a grey tint instead of white; the picture confined to an oval rectangular shape, and then surrounded by means of printing, by an imitation of an india tint; a white sky toned down; and various other effects secured by secondary exposures to light have become familiar to most photographers. There is one fact in connection with the subject which is not, however, so well known, and a knowledge of which is important in securing perfect control over the results to be obtained.

Apart from the sizing of the paper, the proportion of albumen, the nature and quantity of the chloride, and the strength and condition of the nitrate bath, there is another circumstance which materially affects the colour of a print, namely, the kind of light in which it is printed. We have before referred to some experiments we have made in this direction. If a print be exposed in direct sunlight it acquires a redder tint than one exposed in diffused light. In toning each, it is easy to bring them each to the same colour; it is merely a question of a little longer toning for the print exposed in direct sunlight. But if a portion of the same print be exposed to direct sunlight, and another portion to diffused light, and then the whole toned together, it will be observed that the difference in colour always remains, the sun-printed portion of the image retaining the warmest tone. We exposed one piece of paper, part to diffused light, part to sunlight, and a third part was exposed to the concentrated light obtained by focussing the sun's rays on the spot with a lens. The last mentioned portion acquired a somewhat foxy colour, allied to orange; the sun-printed portion assumed a chocolate tint, and that exposed to diffused light attained a purple tint. We endeavoured to get in each as nearly as possible the same depth. The tint each part acquired in printing was persistent through all stages, and in the finished print was well marked.

It follows then that perfect unison of tone in double prints may be secured if it be required, by printing the background, or tinting the sky in a light similar to that to which the print was exposed. If a variety of tint be desired, which may be quite consistent with harmony, it may be easily secured. If the background be required warmer than the image, the negative should be placed in diffused light, and the background exposed to sunlight; if, on the contrary, a cool tone be required in the background, and warmth in the image, the latter will be printed in sunlight, and the background in diffused light. The same principle will apply to sunning down a sky. A difference may even be observed between the tint secured by exposing the print direct to light, and exposing it under a glass, which by its green tint slightly retards the action of light.

This general fact, which may be utilized in ordinary double printing, is sometimes troublesome in combination printing, or producing one picture from several negatives. It may

be that the first negative is exposed to direct sunlight, and then there may be nothing but dull weather, without sunshine, for several days. The print thus exposed to various qualities of light during the printing of different negatives, will never turn out harmonious in tone and satisfactory in general effect. Whether it be utilized and made valuable on the one hand, or whether it be guarded against on the other, it is important to note and remember the existence of such a fact in printing.

INFRINGEMENT OF COPYRIGHT IN PHOTOGRAPHS.

A STRONG impression prevails in some quarters that the recent Copyright Act for securing to photographers the sole property in their own productions is less efficient in practice than it ought to be. On various occasions, when cases of piracy, well made out in all respects, have been brought before metropolitan magistrates, there has been, either from judicial misconception or misplaced sympathy, a failure of justice; the cases have been dismissed, or ridiculously small penalties have been awarded, without costs. In either case the aggrieved complainant who has complied with the law in all respects, and put in operation that part of it especially designed for his protection, is saddled with the expenses of his action, and left without remedy. We had recent occasion to comment on a case of this kind decided by Mr. Yardley.

On Tuesday a charge of piracy was heard at Guildhall upon the general merits of which we shall make no comment, as it is likely to come before a higher court for final decision. We shall, however, briefly refer to one or two questions it raises, which are of interest to photographers. We first quote the brief report of the case as it appears in one of the daily papers:—

GUILDHALL.—THE COPYRIGHT OF WORKS OF ART ACT.—*Mr. Thos. Ordish*, a publisher, of Paternoster Row, was summoned before Mr. Alderman Carter, for unlawfully selling fraudulent imitations of certain registered photographs belonging to Messrs. Southwell, the photographers, of Baker Street, Portman Square.

Mr. Greenwell conducted the prosecution; Mr. Poland the defence.

Some preliminary remarks having been made by the learned gentlemen, the first witness called was—

Mr. Wm. Henry Southwell, who said he was a member of the firm of Messrs. Southwell, photographers, of 16 and 22, Baker Street, Portman Square. They were the proprietors of the registered copyright portraits of Miss Lydia Thompson, in a Spanish dress; and Miss Herbert, as Diana, in Endymion. They had not granted licences to anyone, and consequently not to Mr. Ordish, to make or sell the copies produced, which were spurious imitations of the copyrights.

Cross-examined: They claimed the copyright of the portraits, because they took them from the living originals.

Mr. Limbird Sisman, manager to Messrs. Southwell, said he registered the copyrights in question at Stationers' Hall, on the 3rd of October, 1862. On the 23rd of November last he purchased the two colourable imitations of them at the establishment of Messrs. Bickers and Son, of Leicester Square, where they were sold at 5d. each, the price of the original photographs being 1s. 6d. each. They were very good as copies. He afterwards tried to purchase some at Mr. Ordish's shop, but was unable to do so.

Mr. Poland said certainly not, because Mr. Ordish had previously ascertained they were not legal photographs.

Mr. Greenwell alleged an opposite reason, Mr. Sisman having been recognised as Messrs. Southwell's manager by the shopman.

Mr. Bickers, jun., proved that he purchased the two spurious photographs in question of Mr. Ordish. He had known him many years as a highly-respectable tradesman. He bought the photographs, with others, openly and in the ordinary course of trade. There was no concealment, neither did he receive any caution from Mr. Ordish about them.

Mr. Greenwell said that was his case.

Mr. Poland relied upon the respectability of his client, and the manner in which he had acted on learning that he was doing wrong in selling the spurious photographs, as the strongest evidence to prove that he had no knowledge of a subsisting copyright of the portraits he had been selling. That he had withdrawn them from circulation was clear, as Mr. Sisman was himself unable to buy a single copy when desirous of doing so prior to the commencement of these proceedings. In the absence, therefore, of any proof of a guilty knowledge, Mr. Ordish was entitled to have the complaint against him dismissed.

Alderman Carter said he could only come to the conclusion that the defendant had erred through ignorance; and as he did not continue the sale of the spurious photographs after he became aware of their real character, he should not feel justified in convicting a respectable tradesman of such an offence under those circumstances. He therefore dismissed the summons.

Mr. Greenwell asked for a case to enable him to appeal to the Court of Queen's Bench on the question.

Alderman Carter said: Certainly; he should be pleased to have the point argued by a higher court.

The decision here given is not unnaturally very unsatisfactory to the plaintiffs, and to many others who, like them, possess valuable copyrights in published photographs. One correspondent, writing to us on the subject, concludes that if such decisions are possible the Act is a dead letter, and that piracy may become as rife as it was before the passing of the late Act. There is, however, one very cogent reason why such a result will be impossible. The sole ground of exemption from penalties in this case is the conclusion at which the magistrate arrived to the effect that the defendant had no knowledge of the fraudulent character of the pictures he sold, that he erred through ignorance. Without pausing for a moment now to ask how far the plea is justified by facts in this instance, it is quite clear that such a plea will not be available for the same person a second time. The law, therefore, if not penal in this instance, must at least become preventive of further piracy by the same person.

The whole case here turns on the question of guilty knowledge, and will, no doubt, be fully argued before the Court of Queen's Bench. The clause in the Act giving penalties makes a significant distinction on the subject of guilty knowledge. Persons making piratical copies, or causing them to be made, are subject to penalties without any reference to their knowledge of the law, or of the existence of a copyright in the works. They are presumed not to attempt to obtain an interest in a certain existing property until they have ascertained the legality of their act. But persons selling, importing, publishing, or otherwise

distributing pirated copies, are subject to penalties only if they do so "knowing that any such repetition, copy, or other imitation has been unlawfully made." Here a well-known maxim of criminal law is doubtless intended to apply; *actus non facit reum, nisi mens sit rea*. Criminal knowledge and criminal intent are necessary to constitute criminal action. The plea of ignorance, however, even where established, is only available for the seller, not the producer; it cannot be pleaded in any case if sales are continued after warning from the proprietor of the photograph, and can never be available twice for the same person.

THE TANNIN PROCESS: IS IT SLOW OR RAPID?

BY JOSH. S. HURST.

[Referring to the question regarding the rapidity of tannin plates, Col. Stuart Wortley has sent us a practical answer in the shape of a magnificent study of clouds, and some portion of foreground, taken instantaneously on a tannin plate with the triple achromatic lens. Mr. Hurst, who has been very successful with rapid tannin plates, sends the following excellent remarks.]

PERHAPS a few remarks upon the tannin process, as practised by Mr. H. C. Jennings and "G. W. O.," and published in the NEWS of the 4th inst., may not be unacceptable to your readers.

The first thing that strikes one is the vast differences in time of exposure given by the two operators, and the question naturally arises, What is the cause of the difference of sensitiveness of plates prepared by these processes?

Having made many experiments for the purpose of obtaining rapid dry plates, I think I can point out the reason why those prepared by Mr. Jennings are likely to be more sensitive than the others, though of course the two processes cannot be *accurately* compared, because the whole details are not given in either case; for instance, Mr. Jennings does not name the strength of his bath, nor does he say whether it is acid or neutral. "G. W. O." does not give the focus of his lenses, and aperture used.

I will, however, suppose that the baths and lenses are in both cases equal, and pass on to the collodion. In this there is a difference; Mr. Jennings uses bromo-iodized, and "G. W. O." uses Ponting's iodized, mixed with bromo-iodized. Now I have proved by careful experiments, that (with the same exposure), bromo-iodized collodion gives much more detail in tannin plates, than collodion simply iodized, and this agrees with Major Russell's assertion. See the 2nd edition of his book, page 30.

Here, then, is one cause why I should expect to find Mr. Jennings's plates more sensitive than those of "G. W. O."

The next point for consideration is the preservative.

Now, as tannin has an *acid* reaction, it may be supposed that a preservative containing 5 grains to 1 ounce of water would be less likely to impair sensitiveness than one of the strength of 15 grains.

On looking over my note book, I find that on January 7th, 1863, I prepared fourteen dry plates with various preservatives of different strengths; these were exposed in the same camera under precisely similar conditions of light (having been kept until February 21st, to secure a favourable day), and, after comparing the results, I made the following memorandum:—"These experiments seem to show that a stronger solution of tannin than 5 grains tends to make the film more insensitve, probably from the acidity of tannin."—Major Russell says, "a strong solution slightly diminishes sensitiveness," page 53.

Here, then, is another reason why Mr. Jennings's plates may be expected to be the most sensitive.

We now come to the developers. "G. W. O." uses 3 drachms of a solution of pyrogallie acid, strength $1\frac{1}{2}$ grains to 1 ounce of water, mixed with from 10 to 20 minims of a solution containing 20 grains of nitrate of silver, and 20 grains

of citric acid in 1 ounce water. Mr. Jennings uses a 10-grain solution of pyro (without either silver or retarding acid), until the details are well out. Here, then, is a vast difference; 10 grains of pyro without acid, against 1½ grains with acid, there cannot be a doubt which is the most powerful developer, and this of course is (in the result produced), tantamount to an increase of sensitiveness in the plate.

The requirements requisite for short exposures with tannin plates seem to be a neutral bath; bromo iodized collodion; as weak a solution of tannin as will give sufficient intensity with the sample of collodion used, and a powerful developer.

Mirfield, December 12.

COLONEL STUART WORTLEY'S STUDIO.

In answer to several inquiries, we have been courteously furnished by Col. Stuart Wortley with a ground plan and elevation of his recently erected glass-room, and we add a few particulars of its construction. On reference to the subjoined ground plan, it may be seen that the total length

of the room is thirty-six feet, the portion really constituting the studio, the only part lighted, is twelve feet wide by thirteen feet long. The unlighted portion, in which the camera stands, is twenty-three feet long by eight feet wide, and the extreme end is divided off to form the dark room. The part marked 6 has a tier of shelves for various purposes.

On reference to the sketch of the elevation it will be seen that the studio portion is 12 feet high at the ridge. One side of the studio is all glass, consisting of corrugated glass from the ground to 7 feet high, and from thence to the roof clear white glass. The sloping front light (7) is clear white glass. The opposite side of the studio is opaque, reflected light only being obtained on that side. The roof (4) is also opaque. The only portions having glass are one side of the square or studio portion, and the front sloping portion of the roof (7). With the exception of the glazed parts we have named, the room is chiefly constructed of inch boarding, covered at the roof with asphalt felt. The unilluminated portion is 7 feet high to the eaves and from thence to the ridge about two feet more. The window marked 2 is of orange glass for the dark room. The other small window is to admit a little light when necessary to the unilluminated portion of the room. Each pane in the studio has a distinct set of two blinds, one white and the other black, and the blinds of each pane may each be worked quite independent of the other, so as to secure entire control of the light.

The room is well built throughout and carefully finished in every part, making an excellent smoking room when not used as an amateur studio. The total cost of the erection was £113.

Col. Stuart Wortley informs us that he will have pleasure

in furnishing further particulars to any gentleman who may require them; either through the Photographic News, or, in answer to letters addressed to him direct, at the Carlton Club, Pall Mall.

ALPHONSE DE BREBISSEON'S TREATISE ON INSTANTANEOUS DRY COLLODION.

BY M. ERNEST SAINT EDMÉ.

The great desideratum in photography is a collodion that will dry upon the plate, by means of which we can operate anywhere and at any moment, its sensibility diminishing only with time, although the collodion exists upon the plate only in the dry state. This question possesses sufficient importance to tempt operators to undertake difficult researches in order to obtain its satisfactory solution.

Hitherto we have only succeeded in preserving iodide of silver dry, by removing every trace of free nitrate of silver from the saline films deposited on the plate; but the film of iodide that remains is so parchmented and horny, that it is almost impervious to light and to the developing agents, consequently its sensibility is entirely exhausted. M. Belloc, in one of his treatises, states that dry collodion with tannin is superior to any other hitherto proposed. M. Brebisson devotes a special study to this important question, and we extract from his treatise the principal conclusions at which he has arrived.

Photographers have so busied themselves with the sensitive substances offered by chemistry, that it is almost impossible to present a preparation of any sensitive collodion the efficacy of which shall be due to new products. The discovery of an instantaneous collodion, particularly in the dry state, has always vividly excited the interest of operators; to what substances have they not had recourse to excite this sensibility? Iodide of ammonium, iodide of arsenic, chloroform, aldehyde, the bromides . . . have all been tried. The greater or lesser rapidity in the sensibility depends, we think, upon a concordance, more or less perfect, in the composition of the different baths employed. Instantaneity is, then, a resulting, and not the result, of simple action.

The process described by M. de Brebisson, in his treatise, rests upon the same bases as that of Major Russell, improved by Mr. England. The author has merely modified the preparations, the object of which is to preserve the collodion, dried upon the plate, in its original sensibility; and he says that he has arrived at so short an exposure, that it may be regarded as truly instantaneous.

The author shares our own views when he states that he has not sought to employ new substances, but only to bring the old ones into the most favourable conditions. This new method will not, therefore, augment the photographic pharmacopœa, already too bulky.

We will now proceed to examine this new method in its various phases.

Composition of the Collodion.—It is above all things necessary to have a very sensitive collodion, that works well, as the phrase goes. It may be employed according to various formulæ; for every collodion suitable for the wet process, will be equally so with tannin or pyrogallic acid. Only, the sensibility will be different, according to the proportions of iodine and bromine. M. de Brebisson prefers the following collodion, on account of its sensibility, as well as for its constancy and easy preservation:—

Sulphuric ether at 60°	300 parts
Alcohol at 40°	75 "
Pyroxyline	4 "

To 100 parts of this collodion, become limpid by long standing, add 15 to 20 parts of the following sensitizing solution:—

Alcohol at 40°	100 parts
Iodide of cadmium	10 "
Bromide of cadmium	2 "

Sensitizing.—The collodion being poured on to the plate, and a certain amount of evaporation having taken place, it is sensitized in a bath formed of 7 to 10 parts of nitrate of silver, dissolved in 100 parts of water, with the addition of 5 parts of crystallizable acetic acid.

Washing.—The object of this operation is to remove the free nitrate of silver remaining on the surface of the collodion. If the washing is not complete, the sensitized plate will not keep very long, and spots appear on the collodion film, especially at the moment of the appearance of the picture, sometimes even sooner. A collodion plate, sensitized, and properly washed, and consequently deprived of free nitrate of silver, should, if kept from light and moisture, keep at least two months.

Preserving Coating.—Major Russell employs an aqueous solution of tannin to coat the well-washed collodion film, so as to preserve its sensitiveness after drying. The newer the collodion, the thicker the coating of tannin must be. Mr. England proposes to add honey to this tannin solution. After studying the influence of sugary matters upon collodion, M. de Brebisson prefers to replace them by solid substances, the quantities of which are perfectly known, therefore he employs with much success, barley sugar and jujube paste. He has also recognized, in wishing to recur to gum arabic to increase the solidity of the preserving solution, that this substance possesses the faculty of increasing the sensibility of collodion, and securing its keeping. Once this coating becomes dry, to avoid blisters and cracks, when it softens at the time the picture appears, it suffices to fix the borders by means of a solution of white wax in benzole. This precaution is however, unnecessary, if we replace the honey by jujube paste or barley sugar.

Among the various formulæ for preserving solutions, indicated by the author in his treatise, we extract two, into the composition of one of which tannin enters, and not into the other.

1. Distilled water	90 parts
Alcohol, at 30°	10 "
Tannin	2½ "
Barley sugar	2 "
Gum Arabic	6 "
2. Distilled water	90 parts
Alcohol, at 36°	10 "
Jujube paste	3 "
Gum Arabic	5 "

Exposure in the Camera.—It will be understood that the operation is executed in the usual manner, making use of the ordinary apparatus. Only in the case of an instantaneity, M. Humbert de Molard proposes an apparatus which he calls *Stere-obturator*, or spring shutter-stop. This stop is a sort of blind, of stuff impervious to light, which is extended by means of a spring upon two cylinders placed in front of the objecture. A round hole is cut in the middle of the blind. When the finger is placed upon the spring which governs the fastening, the blind, pulled by one spring, leaves the other spring upon which it was rolled, and for a moment covers the other cylinder. Although this movement of transfer is so rapid that the eye cannot follow it, the aperture in the blind permits the light, during this instantaneous passage, to act upon the sensitized plate contained in the camera. It is by the assistance of this apparatus that M. de Brebisson has controlled the degree of sensibility in his dry collodion to various spaces of time, and, as he states, to have each time obtained as good pictures as if he had made use of wet collodion.

Development of the Picture.—The author asserts, although the contrary has been maintained by eminent practitioners, that this operation may be deferred several days without inconvenience. Still, the certainty of a long keeping after exposure, can never be absolutely attained. Many causes may, in fact, contribute to hasten the reduction, and produce spots—such, for instance, as a sudden elevation of

temperature, imperfect washing especially, and the employment of bad chemicals.

Almost all the baths with an iron base develop the picture quickly, but it is very rarely, says M. de Brebisson, that they are of equal tone throughout, especially when the development is very rapid. These inequalities are due, we think, to an irregular impregnation of the dry collodion. The developing solution of sulphate of iron, acidulated with tartaric acid, as proposed by M. E. Renet, appears to be the most successful.

It is necessary to remark that, in winter, when the temperature of the operating room is rather low, the picture is very slow in making its appearance. It must be accelerated by the aid of heat.

Fixing.—The proofs must be fixed by means of an almost saturated solution of hyposulphite of soda, which must be poured over the surface, until the milky appearance of the collodion film has disappeared, and the cliché has become transparent, without white cloudiness. We next proceed to wash the plate carefully. When the film is dry, apply the protecting varnish.—*Cosmos.*

PHOTOGRAPHIC CHEMICALS :

THEIR MANUFACTURE, ADULTERATION, AND ANALYSIS.

TIN.—This is one of the earliest known metals, and is in many of its compounds of considerable interest. The metal is too well known to require special description here. It occurs in commerce under several forms, the purest varieties being Malacca and Banca tin, and English grain tin. The best tin foil is also pretty pure, although some foil is largely adulterated with other metals. The impurities in commercial tin are arsenic, antimony, bismuth, zinc, lead, iron, and copper. They may be separated by heating tin filings with an excess of nitric acid; this oxidises the metal, and converts it into a white insoluble binoxide. It is well washed with dilute hydrochloric acid, and then reduced to the metallic state by being heated in a charcoal crucible at a bright red heat. In softness, the pure metal is intermediate between gold and lead; it is highly crystalline, and crackles when it is bent. It melts at about 240° C, and boils at a white heat. According to Fridemann, tin may be easily distinguished from other metals to which it is similar, by its behaviour with a solution of gold, containing an excess of hydrochloric acid; a bright surface of tin immersed in such a solution is blackened without evolution of gas; zinc turns black, and liberates gas; lead does not blacken. The most characteristic behaviour of tin is its conversion into binoxide, by the action of nitric acid. Unlike the action of this acid on most other metals nothing is dissolved, but the whole of the tin is converted into a heavy white powder called stannic acid. This is quite insoluble in nitric acid or water, and the reaction is one which is very frequently made use of in the laboratory. If any phosphoric acid is present, it is also retained in the insoluble form by the binoxide of tin, and this fact is frequently used in the estimation of phosphoric acid. Tin and sulphur unite together to form a remarkable golden coloured compound called *aurum musivum* or mosaic gold. The best method of preparing this, is to mix together five parts of protosulphide of tin and eight parts of corrosive sublimate, or to mix a pulverised amalgam of twelve parts of tin, and six of mercury, with seven of sulphur, and six of sal ammoniac. Either of these mixtures is heated in a loosely closed Florence flask, placed in the sand bath. A gentle heat is first applied for some hours; afterwards the heat is raised, but not quite to redness. The greater part of the mosaic gold is found at the bottom of the vessel; the smaller, but purer and finer portion sublimes. Bisulphide of tin prepared in this manner forms gold coloured translucent delicate scales or six-sided laminae unctuous to the touch. Mosaic gold is used in the arts for a bronze powder for touching the edges of painted plaster busts, it is also used by house painters and paper stainers. Tin forms two compounds with chlorine, the protochloride and the bichloride. The former compound, SnCl, is pre-

pared by dissolving pure granulated tin in hydrochloric acid. When no more action takes place, the solution is poured off and evaporated gently until the crystallizing point is arrived at; it is then allowed to cool, and the crystals are separated; they are known in commerce under the name of "salt of tin." This is prepared in enormous quantities for dyeing purposes, the solution being effected on the large scale in copper vessels which are not attacked so long as any portion of the tin remains undissolved.

Protochloride of tin is a very valuable agent for dyers; it is used in calico printing, both as a mordant and a deoxidizing agent. When exposed to the air, chloride of tin absorbs oxygen, forming binoxide and bichloride of tin. Manufacturers prevent this by the addition of chloride of ammonium, which forms a double salt with tin, not so easily oxidizable in the air. Protochloride of tin is of great use in the laboratory for deoxidizing purposes; it is usually dissolved in dilute hydrochloric acid, and when added to solutions of metals reduces them, if possible, to the lowest state of oxidation, or to the metallic state; thus, per-salts of manganese and iron are reduced to the proto-salts, arsenic acid is reduced to arsenious acid; almost all the compounds of mercury are reduced to the metallic state; and silver salts to metallic silver. With gold, protochloride of tin forms a brown or purple precipitate according to circumstances.

Bichloride of tin, SnCl_2 , is prepared by the action of dry chlorine gas on tin foil, or by distilling common salt with persulphate of tin, and rectifying in retorts over oil of vitriol. It forms a thin colourless liquid, boiling at 120°C ., and giving off white fumes in the air at ordinary temperatures. Water unites with anhydrous bichloride of tin with great avidity: with one-third of its weight of water, the liquid solidifies to a colourless mass of crystals, a great deal of heat being evolved, the first portions of water hissing as if they had been poured upon hot iron. The addition of more water dissolves the bichloride of tin, forming a colourless liquid which, when evaporated and cooled, yields deliquescent crystals. This solution is like that of the protochloride, largely used by dyers and calico printers.

Purple of Cassius is a curious compound of tin and gold, the exact composition of it being a matter of some doubt. The best method of forming it is to mix one part of the *liquor ferri muriatici* of the shops, with three parts of water, and a solution of one part crystallized protochloride of tin in six parts of water, added till the mixture acquires a greenish tint, after which six parts more of water are added. On the other hand, some gold is dissolved in hydrochloric acid with gradual addition of nitric acid, excess of acid, especially the latter, being carefully avoided. The solution is diluted so far that 360 parts of the liquid contain only one part of gold, and the tin solution is then added with constant stirring as long as a precipitate is produced. By this process 100 parts of gold yield 360 parts of dried purple. In order to ensure success, it is important that the above proportions be closely adhered to. In the moist state, gold purple is of a dark purple red colour, brown after drying. Whilst moist, it dissolves in aqueous ammonia, forming a deep purple red liquid. When mixed with glass, and melted, the purple imparts a strong ruby colour to it. The analysis of purple of cassius has not yielded good results, owing, no doubt, to the difficulty of obtaining it free from either metallic gold or binoxide of tin. Some chemists consider it a mixture of binoxide of tin with metallic gold, whilst others look upon it as a compound of binoxide of tin and oxide of gold. Recent researches of Faraday seem to lead to the opinion that purple of cassius is simply binoxide of tin mechanically mixed with metallic gold which has been reduced from solution in an extremely fine state of division. It was formerly largely employed in glass staining, the celebrated old ruby glass being coloured with this compound. Much more is thought of this glass than it deserves, and many persons imagine that the art of producing it has been lost, fabulous sums being occasionally paid for small vessels of it. This is quite a mistake, the art of glass staining was

never in greater perfection than it is at the present day; we can not only make ruby glass equal to the old kind, but we can make it far better, and if the employment of purple of cassius for this purpose is not so general as it was formerly, it is because it is attended with great risk of spoiling the glass, whilst other processes are known by means of which an equally good colour may be obtained with no uncertainty whatever.

PHOTOGRAPHY IN ITS APPLICATION TO MILITARY PURPOSES.

BY JOHN SIPLER, F.C.S.*

Assistant Chemist in the War Department.

(Continued from page 597.)

THE cameras, printing frames, and other similar mechanical contrivances used in our department, are in no way different from those in common use. The necessity for providing means of taking pictures at a distance from the photographic laboratory has been met by the construction of a portable dark room, which, at Shoeburyness, is moved as required by two men, who carry it sedan fashion. There is no flooring, but a loose black canvas border on all sides effectually excludes the light. A working bench, with windows appropriately placed, shelves and wooden partitions for the reception of bottles holding chemical solutions, and on the roof a very effective ventilating contrivance, completes the equipment. At Woolwich we have a photographic van, which was constructed and originally used by the Royal Carriage Department. It is four-wheeled, and, being somewhat large in dimensions, is drawn by two horses, which latter are supplied, when required, from the Military Train Service. Some few years ago, this van accompanied the troops from Woolwich to Dartford, and enabled Mr. Butter to produce a series of photographs illustrative of camp life.

Besides these transportable operating rooms, we have successfully used the square tent designed by Mr. Smartt. On several occasions the Artillery Officers have had "field days," both in the grounds of the Royal Military Repository, and on Woolwich Common, and with tents pitched have, under photographic canvas, allowed me to assume the command. Many useful sketches have thus been secured, and out-door experience gained, which has since been further extended by my pupils, some of whom, at distant stations, have given proof of the value which attaches to photography as a ready means of recording faithfully the geographical and military features of a country, or of reporting details of construction, whether relating to stockades, forts, or suggested improvements in military equipment.

It will be perceived that our usual course of operating has been to sensitize, expose and develop the plate on the spot, so that the resulting picture may be examined and approved before returning home, or removing the camera with the rest of the apparatus to another subject. Much progress has been made towards the perfection of the so-called dry processes since the early date at which, in conjunction with Mr. Crookes, I had the honour of announcing the first and necessarily imperfect results obtained upon this system.

Since the proposals referring to the use of the nitrates of zinc and magnesia, in May, 1854, and the employment of honey, recommended shortly afterwards by Mr. Shadbolt, an immense variety of preservative agents have been successively brought under the criticism of the practical photographer, and the results in many instances have testified to the general efficiency and uniformity of such processes; but it is nevertheless true that at the present moment, we are without a guide as to the precise interval of exposure required for the perfect rendering of detail in the diversified range of subjects to which the camera has to be directed. Then, from the inverted position of the image upon the ground glass, we are, at the time of focussing, apt to pass over little inaccuracies which could not escape our observation when examining the finished negative. Under these circumstances we still prefer for general use the wet collodion process, which has, moreover, the advantage of reducing to a minimum the period of exposure, a matter often of vital importance, as we have already seen.

For collodion, we have of late been dependent upon com-

* Read before the Photographic Society, on the evening of Tuesday, December 1st.

mercial supplies; there are now so many manufacturers who offer uniformly an excellent article, that no difficulty has been experienced in procuring collodion of first-rate quality. We have adopted, likewise, the common practice of mixing two samples for ordinary use. I have lately had an opportunity of seeing very good results follow the employment of carbonate of soda as a means of restoring iodized collodion which has become reddened by age. A few drops of the aqueous solution were sufficient for the treatment of a large bulk of the red collodion; and, after allowing time for the subsidence of the insoluble particles, such a collodion appeared to furnish a denser image and to be more sensitive than before. This mode of proceeding is being carried out by Sergeant Inglis, and, so far as I am aware, is novel.

The process of iron development (using a 15-grain solution of the protosulphate), has given us some of our best results; the plates have then been intensified with pyrogallic acid and silver, applied, usually before fixing, but in some instances, especially when the least tendency to fogging was exhibited, afterwards.

The importance of a good supply of pure water for photographic use has been most conclusively demonstrated in the taking of negatives at Shoeburyness. The wells from which the ordinary supply is taken, are close to the shore, and so near the mouth of the Thames that the water contains more saline constituents than usual, with a proportionately large amount of the chlorides of sodium and magnesium. It has consequently been found desirable to wash the finished negatives with distilled water before drying the film, and applying the varnish. Some of the early negatives, taken at a time whilst this precaution was not known to be necessary, have suffered by the cracking of the varnish, and the appearance of moisture under the film. The deliquescent character of the salts left on the evaporation of the water offered at once the full explanation, and no difficulty of this kind has since been experienced.

Whilst upon the subject of negatives, I feel it a duty to bear testimony to the excellence of a plan of intensifying those which have already been varnished, for which we are indebted to Mr. G. Wharton Simpson. The method consists in first softening the film and varnish with alcohol, and then treating with tincture of iodine, the action being carried so far only as to produce an olive layer of superior non-actinic properties.

The printing process adopted in our Department involves the use of albumenized paper for all purposes. Many trials have been made of the new German enamelled papers, and also of the gum benzoin or resinized paper, prepared according to the instructions of Mr. Cooper. The examination of the resulting prints led me to the conclusion that the brilliant lustre of the enamel papers permitted only of their being employed for small pictures, whilst the benzoin paper, on the other hand, although well adapted for large subjects, did not give sufficient details in the shadows to render its general introduction desirable.

The sheets of albumenized paper are usually sensitized by floating upon a 70-grain solution of nitrate of silver, printed and washed, toned by the alkaline gold process, and fixed in plain hyposulphite solution.

The formula for the gold toning bath has usually been—

Chloride of gold	5 grains
Bicarbonato of soda	20 grains
Water	1 pint.

The acetate of soda process has likewise been occasionally employed. The final washing process has always been considered a matter of grave import, and has been carried out with that scrupulous attention which the necessities of the case demand. After a few preliminary rinsings, the prints are washed in a current of water, for which purpose they are transferred to deep gutta-percha or porcelain dishes, having a lip at one corner, which provides for the overflow without permitting the sheets of paper to escape from the washing trough. An india-rubber joint and glass tube delivers a supply of fresh water without splashing, and the produce of the day's work remains in the water during the succeeding night. On the following morning the prints are dried by suspension from the American spring clips. They are then mounted with glue, and passed through Bury's rolling press. Gum-water preserved with camphor has been to a limited extent employed for mounting.

Faded photographs are almost unknown to us; none have yet been reported, and the few prints I have had occasion to

condemn were instances of after contamination, due either to incautious handling or splashes of the hyposulphite solution. I have to regret my inability to remove, by chemical means, the whole of the silver from the protected white parts of albumenized prints, a difficulty to which I invited attention some fourteen months ago. All my efforts in this direction have hitherto been unavailing, and it has not been found possible to remove this small proportion of silver without using powerful agents, which injure the tone or impoverish the character of the photograph.

Our photographic department is at the present time almost in a transition stage, a new building having been erected for us in the Royal Arsenal, one wing of which will be devoted to photography, the remainder being occupied by the chemical laboratories. The new glass room has its chief aspect nearly north, and is partially lighted both on the west and east. The roof is lofty, and the principal dimensions are 25 feet by 15 feet. Adjoining this are two other rooms which will be devoted to printing and general operating, the former being fitted with moveable sashes, glazed with Claudet and Houghton's red "non-actinic glass." The washing-table occupies one side of the printing room; it is lead lined, and provides a water supply to each batch of pictures.

The negative rack is of the ordinary description, with curtains in front to exclude the dust. We have already a thousand negatives in stock, many of them being plates of the largest size, and from these we have issued during the present year to the various Government Departments upwards of eight thousand prints. The majority of these are sent out mounted on quarto cards, tinted of a pale buff, and with a manuscript description appended.

GLASS ROOMS. AND LIGHTING THE SITTER.

BY W. B. PARKER.*

WHEN asked by your secretary to write a paper for this evening, I hardly knew what to write on that would be at all interesting. There has been so much said upon everything photographic, that one is at a loss to find a subject upon which any new ideas may be brought forth. However, upon looking at the *British Journal of Photography* for the 1st instant, and seeing therein a description of a "glass room," it struck me that such would form a good subject for a paper.

Every one has his pet idea of a glass room, but great is the diversity of opinion thereon; one holding out for plenty of top light, another for plenty of side light, while another says "neither of you are right unless you have an abundance of front light." Still, generally, we find it advised that you should have as much glass as you can get.

For my own part I believe that it does not depend on the amount of light, so much as on proper management. I have worked in many glass rooms, and have seen some of the finest things produced taken where the majority of operators would have been unable to get anything passable; and I have seen some of the worst "pictures" I ever saw, taken in some of the finest rooms.

In the discussion which I desire to originate this evening, I hope we may do something towards tracing out a cause for this difference of results; and we shall find, I think, that it generally arises from a want of knowing how to arrange the light so as to ensure the most pleasing, truthful, and artistic results. It would be impossible to give any set rules for controlling or directing the light, because every different sitter necessitates a different arrangement of the light; but still we may, perhaps, suggest some principles upon which to work with some degree of certainty.

It is necessary that the sitter should receive equal illumination, the feet and accessories being well lit. In some rooms, to secure this is very difficult, through not having a sufficiency of side or front light. This I have overcome best by covering the larger portion of the roof over head with tissue paper (of course it has lengthened the exposure). This gives an extraordinary good effect by weakening the light on the top part of the figure, thus allowing you to bring up the whole of the details in the lower part, and securing a more harmonious picture.

Still it is particularly necessary, to avoid flatness and monotony,

* Read at a meeting of the South London Photographic Society, December 10th, 1863.

that there should be one principal light, so arranged as to impinge upon the principal parts of the face. This principal light should not be too strong, or it will destroy softness; and, although you may get excessive boldness, you will not get flesh. In such a room as I have indicated above, this would be comparatively easy, as the head, being nearest the illuminating source, would receive the most brilliant light, and the other parts would fall properly in their place, especially if the room is a long one, or you have a little front light to soften the shadows. This front light I consider very necessary in all rooms. It matters not whether it is literally a front or a side front, but I should prefer the former. Of course it must not be a strong light, but be properly subordinated—in fact, it should answer the purpose of reflected lights, softening and giving details to the shadows (and by that means helping to give roundness and contour to the features); for, if we are to represent Nature as she ought to be represented, we must get details, even in the deepest shades, and this is one of the best means of getting it that I know of in the way of lighting.

I should advise a certain amount of side light if you can get it. It is not absolutely necessary—still it is useful; and we have the power of stopping out light if we have too much. This side light must not overpower the principal light.

I also find a little subdued light between the sitter and background relieves the figure wonderfully, counteracting that inlaid effect we often see in otherwise good pictures.

In respect to the particular arrangement of light, as I have before said, no fixed principles can be given, as each model requires an entirely different one; for what would suit a person with large full eyes would not answer for one with those useful organs deeply sunk into the head. In fact, in the proper judicious lighting of a figure the likeness to a great extent is secured.

With reference to the direction in which the light should enter, as a general rule I find that an angle varying from forty-five to sixty is mostly required.

The prevailing character of the light should be what is called soft or diffused, but at the same time it should be brilliant or forcible, so that it may enter into and have its influence in the shadows to secure detail even in their greatest depths, detail being a necessary element of roundness.

Returning again to the consideration of front light. It has often been said that a front light is addicted to giving flat pictures—for what reason I do not know, unless it be from a general want of knowledge in operators. I think you will admit with me that the pictures of Disderi, Williams,* and your respected treasurer, Mr. Noel Fitch, are anything but flat, and that in all these cases the principal light appears to be a front one. The same remark also applies to pictures by Rejlander, which are so exquisitely round and well relieved, and whose models receive a direct front light falling from above the head, as well as a subdued side front light. I think, then, the "evils," so called of this particular mode of lighting are altogether a mistake.

Since writing the above, I perceive from an article in the PHOTOGRAPHIC NEWS that Mr. T. R. Williams has re-arranged his light so as to secure a little of what may be termed a high side light. Still, that gentleman's principal light is a front

light, entering at a long angle. Perhaps, however, I have said

* It is an error to suppose that in M. Disderi's, Mr. Williams', or Mr. Rejlander's studio the principal light is a front light.—Ed.

enough to show the importance of front light as an artistic desideratum, and one which cannot be discarded with impunity.

In conclusion, I will try to describe how we may build a studio in which all the necessities I have now briefly described may be provided for, and in which we may be able to arrange our light, as the circumstances of the moment may dictate, with the greatest amount of ease and efficiency.

The diagram to which I now call attention shows, you will perceive, a glass room similar to that of Mr. Rejlander's, but with these differences—that there should be two front side windows instead of one, so that we could light from either side as might be most convenient or desirable, and not be constrained to putting the same one side of the face always either in light or shadow. Again, too, instead of being about 5 feet wide, I think they should be not less than 10 feet wide, and fitted with two sets of white blinds and one dark blind, running on rods from contrary ends, so as to secure any amount of light at almost any angle. We thus secure great control over the lighting.

A short time since Messrs. Helsby and Co. recommended, in the *British Journal*, a room, for which they claimed great simplicity and ease in working. Instead of moving blinds, the sitter was to be shifted here or there. I need not point out to my practical brethren the difficulty of getting a nicely-lighted portrait in such a room. Picture the indignation of your sitter upon being shifted now to the right, now to the left, now backward, now forward! and conceive how improving to the expression this would probably be! Surely, the simple moving to and fro of a few blinds would be simpler and easier, as well as more effective.

In conclusion, I may add that, in opening this subject, I hope I may be the means of getting it well aired in a genuine South-London discussion, characterised by its usual animation, earnestness, and good nature. I do not remember that the subject has received any fair share of attention at a society before, and I think it high time that it should now do so, and with this view at once entrust it to the many able gentlemen around me.

GLASS ROOMS.

BY A. H. WALL.*

ALTHOUGH most subjects have received their share of attention at photographic meetings, there is one which appears to have been unaccountably neglected. This one is "Glass Rooms." We started in photographic portraiture with the idea that, as we needed all the light available, the rooms in which photographs were taken could not contain too much glass; consequently, up to the present time, most of our studios have been constructed as if they were intended for greenhouses, the resemblance being not only in the amount of glazed surface secured, but also in the general form commonly adopted.

Mr. Sutton was, I think, the first to point out this blunder by giving a diagram of a room which was a glass room in name only. It contained a long dark passage for the lens and camera, a front top light and side light, and most of my hearers have doubtless seen diagrams thereof. I had long held similar ideas with regard to the proper form of such a room, and finding that Mr. Sutton had done little more than describe the room in question, I set myself to work, and gave my reasons for the belief that was within me in a couple of "Bits of Chat" in *The British Journal*. Somewhere about the same time Mr. Rejlander—in whom, I believe, the same thoughts had been long lying dormant—carried out his ideas, which resulted in a glass room of the principles advocated by myself. Mr. Lamb, of Aberdeen, also wrote to me shortly after the publication of the remarks I had made on the subject; and, on my sending him a rough sketch of a glass room with comparatively little glass in it, he wrote by return, saying that it was just such a room as he had already erected, the only difference being in the fact that he had a glass room at either end of the dark passage in which the lens stood, so as to secure the choice of two aspects according to the necessities of the weather, or the requirements of sitters. Afterwards I gave similar designs to several correspondents who had read the articles I had written on the subject, and were desirous of carrying out the ideas therein developed.

From some of these I have since received communications,

* Read at a Meeting of the South London Photographic Society, December 10, 1863.

which tend to show that the old-fashioned conservatory-like room is a decided mistake, and that for the purpose of photographic portraiture a little *good* light is very superior to a large quantity of it. Mr. Rejlander's experience goes in the same direction, I am informed; and Mr. Lamb's pictures fully bear out the value of that principle, being clear, round, and brilliant, with well-marked but delicate transparent shadows, and an amount of relief not often seen in ordinary photographs.

But I would not recommend the amateur to conclude that, because such and such pictures were produced in a room of this or that description, therefore they have only to secure a similar room to get a similar result. This would be in every sense a great error; for, even supposing an equality of skill, the why and wherefore may yet be as closely associated with many other things as with the peculiar arrangement and amount of light. Mr. Rejlander's room answers admirably well where it now is, but brought into, say the city of London, it might not be at all a desirable building for photographic purposes. I do not say positively it would not, but it might not. The spot selected for the glass house has, remember, its own peculiar features, and these should be duly considered before we decide upon the kind of building it may be desirable to erect. Before deciding, moreover, the photographer should make himself familiar with the different aspects assumed with regard to the light during the changeful day and varying seasons. For instance, it is well known that many rooms may answer admirably during the summer and be useless in the winter—may be worked in with pleasure during one part of the day, and defeat your best efforts during the remainder.

Instead, therefore, of speaking of this or that as the most desirable form of glass room, I shall just briefly refer to a few very simple facts as guides to principles upon which the beginner may form his own ideas as to the best kind of studio for this or that particular locality.

If you want soft pictures which shall not lack brilliancy and force, and desire at the same time to get such pictures with very rapid exposures, you can question yourself, say thus:—"The more pure and powerful the light the better for my purpose. The light which reaches me direct from the sky is purest, and also the most powerful. How can I get this? These trees shut it out there; that house intercepts it here. When the sun is so high, I shall get it; and when so low, I shall miss it. When the sun is there, the best light will come from such a portion of the sky; when there, from such another portion," &c., &c. By this means you may reach a final conclusion which shall decide where your glass room should stand, what aspect it should have, where you had best put your glass, and how large a surface of it will best enable you to catch the best light at different hours of the day and months of the year.

Well, having chosen your plan for a glass room of the kind required, you turn to other considerations. The nearer the light to the sitter the more power will it have, and, consequently, the shorter the exposure will be; but then the balance of power between the lighted and the shadowed sides of the face will be unequal, and, think you, "the lighted side will be isolated before the shadows are out, and I shall get flat, hard, inartistic, that is to say, unnatural effects. How is this to be avoided?" Clearly by letting in a certain small quantity of light to the shadows, and thus diminishing the contrast of power (the relative strength of the light used for the end desired being tested in the only way it can be tested, viz., by experiment). For this purpose I think nothing is better than a certain amount of front light falling more or less downward.

Desiring brilliancy, and knowing that such a quality is not altogether dependent upon chemical conditions, we next think a little on this subject. If, when the sun is out, you let it stream in through a small aperture, and fall between your camera and an object in the room, and then take a picture of such object, you will find that, while the portion of the object seen through the rays of strong light is tame and weak, the other portions are forcible and clearly defined. This shows us how the lesser light on the object is lost in the greater light intersecting its path from the image into the camera; and we have here a hint of no small value, telling us that the more dominant the light on the image over the light filling the space it traverses in reaching our sensitized plate, the better our resulting image. Then how can this be best attained? I should say by excluding all light which does not pierce fall upon the model; and if you ask how this is best done, I should answer by keeping all the light used *in front of the sitter*. If the light enter at the side of the sitter, the angle at which its more direct rays travel, changing

as the sun shifts its position, will fall, now *upon* the sitter, now *between* the sitter, and now *towards* the lens. If the light enter at the top, it is subject to the same changes; but if both top and side light be also front lights, we defy the shifting rays, and secure the light upon the model an uninterrupted reign of superiority.

I had written thus far because I had reason to fear that, in consequence of illness, Mr. Parker's paper would be found wanting, and I was anxious to preserve the reputation of our committee for never letting the members return home disappointed. Mr. Parker's paper, however (as a letter just received informs me), being ready, I need not carry my task further, and shall submit the above to consideration as part of my portion of the discussion which that gentleman's communication will doubtless create.

MOUNTING PHOTOGRAPHS.

M. H. KIMBALL'S PLAN.

Trimming the Print.—For this purpose there is needed a glass plate of the desired form and size of the print, a good penknife, and a thick sheet of plate glass, six inches or more square. The sides should be exactly vertical. This form need not be of plate glass, and it is even better that it should be slightly curved, so that when laid on the print, concave side down, the end edges will first fasten the paper, and by gentle pressure on the middle the whole surface of the glass will be in contact with the paper. The blade of the knife should be thin and of high temper. The operation of trimming consists in laying the print down, impression up, on the plate glass, upon this the glass form, and then cutting away the paper protruding from the form. The cut should be made with a free hand, each cut taking away the whole of the paper from one side. With care this apparatus may last years. If from carelessness, however, the edges of the glass become nicked, it is useless, and a new one must be procured. These glasses may be obtained from the photographic dealers. The print thus trimmed is ready for toning. (We take it for granted that intelligent operators understand that prints should be trimmed before toning, in order to save the silver from the paper clippings.) Prints are also trimmed, and more expeditiously by means of a steel cutting die; of this plan more in future. The trimmed prints toned and dried are ready for

Kimball's Improvements in Mounting.—Procure a block of wood a trifle smaller than the desired size of print, and about three-quarters of an inch thick; through the centre of this block drive a long nail, so that the head shall be flush with the surface. Next cement with sealing wax upon the top of the block a glass plate of a size a trifle larger than the block. The top of the table on which the block is used is pierced with gimlet holes at convenient places, into which the nail of the block fits, thus keeping it snug in its place. For use, the block is set in one of these holes; a piece of cotton muslin of two thicknesses is dipped into a tumbler of water, gently squeezed, and laid on top of the glass. Upon the wet cloth the print is laid, impression down, and the paste (Mr. Kimball uses gum arabic) is laid on with a broad, flat brush. The cloth needs to be constantly damp, but a wetting for about each two dozen prints is found to be sufficient. If the prints are not thoroughly dried after toning, the cloth need not be dampened so often. After pasting, the prints are attached to the cards in the usual way. The effect of the damp cloth is to make the paper flatten out under the paste, and to prevent the cockling of the card on drying. By having the glass plate only the size of the print, the paste is not wasted, and makes no mess, and there is little danger of its getting on the surface of the print.

Mr. Kimball has often had cards mounted at the rate of twenty dozen per hour.—*American Journal of Photography.*

Proceedings of Societies.

SOUTH LONDON PHOTOGRAPHIC SOCIETY.

THE usual monthly meeting was held on the evening of Thursday, December 10th; Mr. Sebastian Davis in the chair.

The minutes of a previous meeting were read and confirmed, and the following gentlemen were elected members of the Society:—Messrs. Aldis, W. B. Parker, Collis, Walmsley, Everett, and F. Yorke.

Mr. Ross sent for exhibition two very fine portraits, by Messrs. Southwell Brothers, of the size they have termed "imperial." The portraits were those of Miss Kato Terry, and Mr. Fechter, as *Hamlet*. The background and accessories illustrated the value of a skilful combination of real objects with scenic effects. The lens was one of Mr. Ross's portrait combinations of six inches diameter, 24 inches back solar focus, and was used with a three-inch aperture, the exposure being about one minute in a good light. Mr. Ross also sent some interiors of the Crystal Palace taken with his No. 2 triplet of 9 inches equivalent focus; the stop used was the 4-tenths of an inch in diameter.

Mr. H. COOPER, jun., exhibited some very charming card and other pictures, chiefly artistic studies, with fine effects of double printing. The cards were described as produced by Dallmeyer's stereo lens, and the larger pictures with the No. 1 triple of the same maker.

Mr. WHARTON SIMPSON exhibited two card pictures by Mr. Pouncey, produced by his printing-ink process. The Chairman called especial attention to the successful results obtained in the face of all the difficulties involved, and the pictures were generally admired.

Mr. ALDIS exhibited some enlarged pictures produced with the solar camera and the oxyhydrogen light, which excited much attention.

After a vote of thanks to the gentlemen exhibiting specimens, Mr. WALL read a brief contribution from Mr. Walter Woodbury, well known for his fine photographs of Java, whose description of photography in that island will be remembered by our readers. He described a process of printing a picture from two negatives as follows:

Suppose it is required to introduce portions of two negatives into one picture, two sheets of talc are produced the size of the negatives, and on each are painted in Indian ink the part required from each negative. These are used similarly to the paper screens generally employed to shield the paper in double printing, but possess the following advantages. They can be cleaned and used over and over again, and can be placed exactly over the corresponding part in the paper, thereby giving no white line, and do not contract or expand as the paper shield often does.

Where it is required to cover some delicate part, such as a lock of hair, lace, or anything that it would be impossible to cut out evenly on paper, there is no difficulty in painting out such part on the talc.

Another method of using it is this:—Suppose you have a portrait to which you wish to introduce a background from another negative. You first block out all the background of the negative, and having prepared the sheet of talc as a dry plate, you take on it a print from the blackened negative, which by over-exposing gives you a shield the exact counterpart of the blackened negative.

Owing to the thinness of the talc no diminution in sharpness takes place.

Regarding Mr. Warner's suggestion for a camera for India, from my long experience there I should think it would not answer, as the slightest moisture inside the camera would keep the lens in a continual steam.

Nothing answers like a piece of black velvet thoroughly damped and laid over the camera, as the rapid evaporation keeps the plate cool and moist for a considerable time. With the thermometer over 95° I have often kept a plate wet for ten minutes.

Mr. WALL then read a paper by Mr. Parker on "Glass Rooms and Lighting" (see p. 606).

The CHAIRMAN, in inviting discussion, expressed his admiration of the glass-room and management of light of Mr. Williams, in Regent Street. He thought the square shape and large size, 30 feet each way, was of great advantage in permitting the sitter to be placed in any desired position, thus meeting the important question of the aspect of the light. He

had his own little glass room, and had tried placing it in all directions. In reference to the question of aspect, the part of the day in which it was most likely to be used was an important consideration. For instance, with a south aspect it would be almost impossible to work between the hours of eleven and one. For professional photographers requiring to work during the whole day, a northern aspect was undoubtedly best, and the light reaching the sitter at an angle of from 45° to 60°. He recommended persons interested in this question to experiment with a white bust, by which the actual effect of lighting would be most easily seen. With a direct front light only it would be seen to be quite flat, but with a light reaching it at a suitable angle the whole would be seen in perfect relief. Perhaps before proceeding to the discussion, it might be convenient if Mr. Wall read his remarks on the same subject.

Mr. WALL then read a paper on "Glass Rooms" (see p. 607). Referring to a direct south light, he said Mr. Rejlander could work with the sun direct on his model, but in that case it was received through the blinds, which were pulled down.

Mr. SIMPSON, referring to Mr. Parker's remark that the subject of glass houses had received so little attention in society meetings, observed that probably no reason why the subject before the meeting was so little discussed was that it was so difficult to treat in the abstract. He was much struck with the truth of this opinion by the paper of Mr. Parker, read that evening, in which that gentleman, referring to the recent alterations in the glass house of Mr. Williams, said that they produced a principal front light, while Mr. Williams's object had been to avoid this, and obtain a high side light, or what painters call "a side front." In reference to the sun's direct rays, which could scarcely be avoided with a southern aspect, he might remind the members that Mr. McLachlan had patented an arrangement of blinds with the express purpose of working with a southern aspect. From the description published it was not very easy to understand the exact nature of the contrivance proposed. He, however, recently had an opportunity of talking over the subject with Mr. Mayall, who had seen the arrangement in operation in Manchester. This gentleman had been so much pleased with them that he ordered them to be adapted to his new glass room in course of erection at Brighton. To use Mr. Mayall's expression, the light was so arranged as to act as an "artificial cloud," and in whatever position the sitter was placed, an intense reflected light might be thrown on him. A southern light, when it could be used, was of course very valuable from its power.

Mr. WALL had tried Mr. McLachlan's plan, and was much dissatisfied with it. All portions of the blind gave off reflected light at different angles, and the image on the ground glass was deficient in clearness and had a woolly appearance. He had hoped to obtain cast shadows by direct light; but the arrangement so altered the light that he got no shadows. He believed, however, that Mr. McLachlan's room was loftier than his, and in a better locality, and these points would have to be borne in mind.

Mr. SIMPSON asked if Mr. Wall really used Mr. McLachlan's arrangement of blinds? or, whether he had only carried out his instructions as well as he could from the descriptions?

Mr. WALL had not had his blinds from Mr. McLachlan, but had endeavoured to carry out the idea himself.

Mr. SIMPSON said that was doubtless the source of the error. Probably Mr. Wall had as much misconceived the real arrangement as he (Mr. Simpson) had done. He had objected to Mr. Mayall that the arrangement struck him as calculated to give a series of small lights instead of one volume of light. Mr. Mayall had assured him of his error, and stated that the results were the finest in point of lighting that he had ever seen. He had heard of others making sets of blinds on what they believed to be Mr. McLachlan's plan, and abandoning them; but he conceived that in these instances they had failed in getting the effect of the genuine arrangement.

After some further conversation on the subject—

Mr. SIMPSON said he was unable to explain the precise arrangement. So far as he understood it, there was a series of narrow strips of wood, hung at right angles to the glass roof, which was placed at an angle of 45°. These were connected, and could be adjusted so as to stand at any position. There was one very important point to be remembered in connection with this subject. However perfect the glass house and arrangements for lighting, they would be of little service to persons who had not an intelligent appreciation of the principles upon which the model should be lighted, and a per-

ception of the right effect when they saw the model lighted. In illustration, he might point to the very burning strokes by Mr. Cooper, then on the table, which were admirably placed, and yet these were produced in a small ordinary conservatory. He was demanded in discussing a question of this kind, of the story of a certain celebrated painter, who, being asked by a pupil with what he mixed his colours to secure such beautiful tints as the painter's answer was, "With brains!"

Mr. COOPER described the position of his room, and his mode of using it. His light was chiefly from the south, and the shade could be used as well over the head of the sitter.

After some further conversation, in which Mr. Simpson referred to the charming and perfectly lighted pictures Mr. Beauchamp had recently exhibited in the room.

Mr. BEAUCHAMP described the method he had adopted to make a conservatory for the purpose of a photographic studio. (See THE PHOTOGRAPHIC NEWS, p. 256.) He remarked that if his room were wider and allowed him to place the sitter diagonally, it would be a great improvement. So far as his judgment and experience went, he protested emphatically against the use of a front light as being either an error.

A conversation followed as to the precise meaning of the term front light. Mr. WALKER defined it as any light in advance of the sitter, whether in the shape of a side window or not. Messrs. Simpson and Beauchamp defined a front light as that from a window in front of the sitter; that from a side window a side light, sometimes from its position becoming a side-front light.

Mr. SIMPSON remarked that if the light at the side seemed to be a side light because it was in advance of the sitter, a side light could not be more than a foot in extent—in fact, the breadth of a man's body. Popularly understood, a side light was that from a side window.

Mr. EVANS, referring to the use of tinsel paper, said, if you do with starch, it speed well. He had 500 or 600 square feet of it.

Mr. COLE referred to the use of tracing linen as much superior to tinsel paper, being very transparent and efficient for the purpose. It was to be had seven yards long and one yard wide. He also recommended the use of spring rollers for black wood without the starch. He would have the boards for the roof to pull up instead of down, and those for the sides to roll laterally.

After some further conversation.

Mr. HART exhibited a model of a small glass house. It was constructed on a plan in general principle similar to that of Mr. Beauchamp, Mr. Matthews, and others, the chief modification consisting in the front part of what may be termed the studio, sloping both at sides and top, towards the narrow, unillumined part.

Mr. SIMPSON, referring to the model as excellent in plan, remarked the principle upon which it was designed was now becoming almost universal. He then briefly described the construction of Col. Stuart Wortley's glass room (see p. 256), which cost £110.

Mr. HART said a house constructed after his model, 24 feet long, the studio portion being 18 feet by 12 feet, and the summer back part 14 feet by 4 feet, the height of the studio 5 feet to the eaves, made of glass and iron, would cost £20.

Mr. HART said a glass house was necessary to protect the sitter from wind and weather, but very fine portraits could be taken in the open air. For his own part, he would have as much glass as possible, and make the studio like a landscape conservatory well supplied with drapery for exclusion of unnecessary light. Drapery had many advantages over blinds, in permitting a variety of arrangements.

The CHAIRMAN referred to the lighting of models in the new series of rooms at South Kensington, and recommended photographers to inspect it.

After some further conversation, the CHAIRMAN announced that at the next meeting Mr. Cooper would read papers on "Weak Printing Baths," and on "Formic Acid in the Developer."

The proceedings then terminated.

REFLECTING SCREENS.—A correspondent has sent us a specimen of silvered paper sold by the fancy stations, which he has found very valuable for covering or shading screens and ceilings when it is necessary, a large amount of reflected light.

Correspondence.

CHROMO-PHOTOGRAPHY.

SIR.—In reply to the letter of Lieutenant-Colonel C. Barrett I beg to say that I have not carefully examined the process which the above gentleman has invented, nor will any one who knows the printing process and the colour it yields in its several stages of exposure say I was wrong in thinking it impossible to produce by the new invention tints so beautiful and so true to nature as may be applied by the artist's brush.

With regard to the art of "producing pictures in the natural colours of the objects by the agency of light," the invention not only does not look like a step in advance, but it is no step in advance with it, because light has not more to do with the production of the various tints obtained by the application of chloride of gold to the prints than it has to do with the printing process in general.

The invention is certainly an ingenious application of the variety of tints which various films of exposure to the gold solution yield, and as such it no doubt deserves appreciation, and will be appreciated according to its merits, but when such an invention is brought forward as belonging to an art which it has nothing to do, it is liable to be mentioned in the manner which seems to have roused the indignation of the gallant Lieutenant-Colonel.

I do not feel inclined to answer to the remainder of the letter, only the passage where it says of photographs coloured by hand that they are "nothing but an abortion not worthy the name of a picture or a photograph," reminds me of the lovely coloured portraits I have seen in Mr. T. R. Williams's room, and seems to prove that the gallant Lieutenant-Colonel cannot have seen anything like them, or else he would certainly not stigmatise them like that unless he had put all his taste into his chloride of gold solution.—I remain, dear sir, yours respectfully,
AROTER BESCH.

THE DISCOVERER OF THE PHOTOGRAPHIC USE OF BROMINE.

SIR.—I am certain the photographers over the country will make a handsome response to the appeal in behalf of Mr. Goddard. I don't think all was done that might have been for the Archer Fund, not from unwillingness on the part of photographers to give, but neglected in the hurry of business.

To obviate this occurring in Mr. Goddard's case, I would suggest that a person be appointed in every town to call upon his fellow photographers and show an name, I hope, but would put their hand to their pockets, and give their mite, but who would put off and perhaps bring their neglect to mind their subscriptions. If it is true that many are making splendid fortunes, let them think and act justly to the man to whom they are so much indebted, and let many who are making a good small living but slowly begrudge to give the price of one dozen "cartes." —Yours truly,
JOHN HENDERSON.

Perth, 14th December, 1863.

Photographic Notes and Queries.

NITRATE OF SODA IN THE PRINTING BATH.

SIR.—Will you allow me to inform your correspondent "Another Photographer's Assistant" that the plan seems to be complete of in his sensitizing bath of nitrate of silver and nitrate of soda are easily explained, and easily remedied, thus:—The nitrate of soda was bad, being feebly alkaline, and an excess of soda or carbonate of soda would, of course, destroy the solution; if he adds a little nitric acid the reaction of the bath is, of course, not at first, but it takes a long time before all the free soda in the bath of the solution has taken by the nitric acid, therefore the reaction being at first good, will become alkaline again after a certain time, if not sufficient nitric acid

has been added, just in the same way as may be experienced in neutralizing a nitrate of silver bath with oxide of silver. It is hardly to be wondered at that the paper, being exposed to nitric acid, free soda, free carbonic acid, and being on the solution while such a chemical reaction takes place in the same, will turn all sorts of colours.

The best remedy for the complaint will be to get good nitrate of soda; but if he has not got it, add nitric acid to the bath in small quantities, and let it stand, frequently stirring for a day or two, then test again, and if it has not a slightly acid reaction add a little more acid, and let it stand again, until it is permanently acid.

Hoping this hint may be of use to your correspondent, I remain, dear sir, yours,
AUGUST BUSCH.

SIR,—On reading "Another Photographer's Assistant's" communication, I quite agree that it is unaccountable his prints becoming green. I should recommend that he brings his bath to a boiling temperature, add its bulk of water, then forty grains to the ounce of nitrate of soda (i.e., if he is certain that it contains eighty grains of nitrate of silver), add nitric acid till slightly acid. If this does not get him out of his difficulty, the fault must be in the paper, or "Photographer's Assistant" has got something else in it (his bath). I have always obtained the best results by having double (at least) the quantity of nitrate of soda to that of silver.

By-the-bye, I have lately had a troublesome negative bath (pin-holes in millions). I added its bulk of water, filtered out the iodide, evaporated nearly to crystallization, made it up to more than its original quantity and strength, added water to the collodion, got fresh iron collodion, acetic acid, &c., with no better results, when I hit on the following "perfect cure;"—To each pint of bath I added an ounce of prepared chalk, shook and filtered, then added acid nitric till the bath worked clear. No doubt there was a quantity of foreign matter in the bath, which all previous treatment failed to remove.—I remain, sir, yours respectfully,
PUBBLICO.

P.S.—I may state that I sunned and neutralized the bath with no success.

London, Dec. 14th, 1863.

DEAR SIR,—I think that, as a photographer, "Another Photographer's Assistant" should have known better than to expect to obtain the same results as others if he did not strictly adhere to the formulas given. Now, if he will refer to the first published formula, he will find that "Pubblico," (PHOTOGRAPHIC NEWS, April 24th), insists upon an excess of nitrate of soda being present if we are to obtain the best results, and the Editor's remarks thereon confirm the same. "An Amateur," in the number for July 17th, gives the same formula, and speaks very highly of it. Again, in the number for October 16, we find a formula still with an excess of nitrate of soda, as also in the numbers for October 30th, and December 4th. Your correspondent himself seems to know that it should be so when he mentions the one who gets prints of unsurpassed brilliance on an 80-grain soda and 30 or 40-grain silver bath, and yet, in the face of all this, he makes a bath by adding 30 grains soda to a 40-grain silver bath, and then wonders that he does not get good results. In the next place it would be well if he took the advice of the Glenfield starch manufacturers, and when he asks for nitrate of soda "see that he gets it," for the latter part of his letter reads very much as if he had been supplied with a sample of common soda instead of nitrate of soda; and if such was the case he cannot be surprised that it should dissolve off the albumen. I would advise him to try again, with a fresh example and an excess of the same in his next bath. Enclosed are three prints on Schering's albumenized paper from the same negative. No. 1 floated four minutes on solution, 60 grains nitrate of silver to the ounce, without any other addition whatever. No. 2, floated five minutes on solution, 35 grains nitrate of silver and 80 grains nitrate of soda to the ounce; and No. 3 floated 30 minutes on solution, 5 grains nitrate of silver, and 60 grains nitrate of soda to the ounce. They are all toned and fixed in the same bath. Please say what you think of them as the productions of a
GREENHORN.

December 15th, 1863.

[Those with the weak solution of silver are certainly equal to that with a 60-grain nitrate solution.—Ed.]

ELECTRIC LIGHT.

SIR,—I am sorry to say my progress with Ruhmkorff induction coils, about which I wrote some time ago, has been but a poor one up to now, for the following reasons:—

Firstly, my time has been too much taken up by my business, so that I could not possibly devote to the subject the attention I could have wished to give it.

Then, of the two makers of coils whom I know, the one did not seem inclined to push the matter, and the other will have all his hands occupied for two or three months to come, by a large order for Australia, so that he could not undertake any fresh orders, nor had he any stock on hand. A good friend of mine in Birmingham, who is a very skilful photographer, wished to make some experiments, and saw the latter maker several times, but, at the time that I thought he was experimenting, he wrote to say he could not get a proper coil to do it with. I applied to two London firms, not makers, but was asked such prices for the apparatus, that I did not think of recommending them. Up to now, I have not been able to find out any London maker; I dare say there are several, but I do not know them. Thus I have been compelled, to my great regret, to disappoint those correspondents who take an interest in the matter.

Mr. T. R. Williams told me some time ago, that he has made a series of experiments with the Ruhmkorff coil at the Polytechnic long since; of this I was not aware when I wrote my letter, or else I should of course not have thought of recommending attempting to use the light for portraiture. Still, for printing purposes, it may do nevertheless.

Should I find out a respectable London maker of coils and batteries, I shall not delay communicating it to those correspondents who have applied for it, for I still think those coils, and the powerful light they give, may be advantageously applied for printing purposes.—Believe me, dear sir, your obedient servant,
AUGUST BUSCH.

Talk in the Studio.

A "LIFT" IN A PHOTOGRAPHIC GALLERY.—An action was tried a few days ago, in the Court of Common Pleas, to recover the price of a "lift," intended to raise sitters from the basement to the top of the house without the trouble of walking upstairs. The plaintiff, Mr. Gerish, an engineer and ironfounder, carrying on business at East Road, Hoxton, sued the defendant, Mr. Bernstingl, a photographic artist, in Regent Street, to recover the sum of £55 for making a lift and fixing the same on the defendant's premises. The defendant's photographic rooms being at the top of the house as usual, for the purpose of obtaining the light, it occurred to the defendant that it would be an accommodation to his customers if the fatigue of climbing up the stairs could be avoided, and he put himself in negotiation with the plaintiff, who has been accustomed to make lifts, or small ascending rooms, wound up by chains and machinery from below to any required height, for houses in the city. The plaintiff, in February last, agreed to make a lift for the defendant for £50, and the extra £5 was for cutting away brickwork, &c., in order to fit the same. The lift was made and fitted, and tried, and found to work, six persons being elevated thereby to the photographic room. The defence to the action was that the lift was so defectively made as to be useless, and incapable of being worked easily, and that the plaintiff had been required to take it away, and that it was now at the defendant's premises only a nuisance. The evidence on the part of the defendant was to the effect that though a person might be raised up to the defendant's room, yet it was by a series of jerks. The jury ultimately found a verdict for the plaintiff for £55, the learned Judge reserving leave for the defendant to move to reduce the amount of the verdict upon a point of law made by Mr. Joyce.

ARTIFICIAL LIGHT FOR ENLARGEMENT.—Mr. Aldis, of Baker Street, has recently shown us some excellent enlargements produced by an adaptation of the oxyhydrogen light to the solar camera. The exposures range from half a minute to 10 minutes, depending upon the amount of enlargement. Development printing is of course used, but an exceedingly good tone, free from the unpleasant green tint sometimes seen, is obtained. The capability of successfully using artificial light for enlargements, instead of waiting for direct sunlight, cannot well be over-estimated in a country where sunshine can never be guaranteed.

THE GODDARD RELIEF FUND.—Photographers are earnestly requested to respond early to the appeal made in our last, in favour of Mr. Goddard, the discoverer of the photographic use of bromine. Subscriptions already received will be acknowledged next week.

ROYAL PORTRAITS.—We have received from Messrs. Southwell Brothers, some very pleasing portraits of various members of the Royal Family, recently taken at their studio. They consist of the Prince and Princess of Wales, the Queen of Denmark, the Princess Dagmar, and the King of Greece, in various single portraits and groups, some of which are very fine indeed, notwithstanding the unfavourable weather in which they were taken. We believe that the lens used was Ross's No. 3 card lens.

TRACING LINEN FOR BLINDS.—Mr. Cole has courteously forwarded us some examples of the tracing linen to which he referred at the South London meeting as being valuable in shutting out direct rays of the sun, without excessive diminution of light. One sample is labelled "very old," but is still perfectly white. Another article called "tracing cloth," is more opaque, and turns yellow with age. The tracing linen is thin and delicate, and more transparent than tracing paper. It is to be had of various widths, 18, 28, 36, and 41 inches wide.

PHOTOGRAPHY IN CAPE TOWN.—Mr. Arthur Green, a correspondent in Cape Town, sends us some very interesting card-portraits and remarks:—"The best collodion that I can find is one I make myself; it is bromo-iodized, consisting of iodide of cadmium and ammonium, and bromide of cadmium, the latter in the proportion of one and a half to two of the combined iodides; developer, double salt of iron and ammonia, 30 grains; formic acid, 10 minims; water, 1 ounce; alcohol, *quantum sufficit*. Intensity with the formula you give, of 5 grains iron, 10 grains citric acid, water 1 ounce; and, if necessary, after fixation, with ordinary pyro and silver solution. Russell's original tannin solution is found by the majority of operators here to be preferable to the tannin and honey, as being more certain; and although my experience has not been very great, still I can endorse this general opinion.

PHOTOGRAPHS AT SOUTH KENSINGTON.—It is stated that the sale of photographs of Raffaele's Cartoons and other works, formerly conducted by the Science and Art Department, has been handed over to the usual trade publishers. Messrs. Chapman and Hall are the chief agents. The effect of this step has been very nearly to double the price. The Department in future will only issue to the Schools of Art in connexion with it.

To Correspondents.

**** PRESENTATION PRINT.**—With the PHOTOGRAPHIC NEWS of January 1st, 1864, we shall present each of our subscribers with a beautiful specimen of Mr. Duncan Dallas's process of photo-electric engraving. This process has been universally acknowledged to be the most perfect method of photographic engraving yet discovered, possessing perfect half-tone and gradation with great force and vigour. The subject is the "Banqueting Hall, Kenilworth," from a negative by Mr. Francis Bedford, the size of the print just permitting it to be used as a page of the PHOTOGRAPHIC NEWS. The print will be from a plate untouched by the graver. It will be printed on toned plate paper, and will be valued as a charming picture, as well as an interesting illustration of a valuable process.

TO AGENTS.—As there is reason to anticipate a large demand of the No. for January 1st, agents are requested by the publisher to send their orders for extra copies as early as possible.

PLATO.—The silver in your hypo bath must be precipitated as a sulphide, by the addition of liver of sulphur. The silver in the washing water must be precipitated as a chloride by the addition of hydrochloric acid, or common salt. The gold in your old toning baths may be precipitated in the form of metallic gold, by the addition of protosulphate of iron. You will find detailed instructions for these processes, and for reducing the metal, in our YEAR-BOOK, which will be ready in a few days. 2. So far as we can see, the irregular tint in the sky of your stereo print is simply due to a similar irregularity in the negative. 3. Formic acid is valuable in dull weather. The proportion can only be decided by experiment, as various samples differ so much in strength.

GEORGE STANHAM.—So far as we can see, there will be no difficulty in obtaining a good position for a glass house at the top of your house. See papers and discussion at the South London Photographic Society, reported in the

present number; also, article on the subject in our forthcoming ALMANAC. 2. A strong iron developer is the best for winter. 3. Transparencies for the magic lantern may be taken by the wet process, but they require toning. See article on the subject, by Mr. Blanchard, in our ALMANAC. JOHN KEYNOLDS.—We believe Marion and Co. make albums for 10 by 8 pictures. Possibly also Solomon or Bourquin.

JONAH.—You may take landscapes with a card lens, if you use a small stop. 2. All the collodions you name are very good; perhaps a is the most sensitive. 3. We are not familiar with the stocks of second dealers; but we don't think it probable, as a rule, that you would save much by purchasing second-hand dishes and pressure frames.

R. G.—We do not know of any one at present, but will remember. **J. S. W.**—We strongly suspect that you have used carbonate of soda instead of nitrate, which would precipitate all your silver as you describe. See letters on this subject in the present number.

EXPOSURE OF TANNIN PLATES.—A. A. sends us two prints from tannin negatives which received from 20 to 25 minutes exposure on a bright day in September, with Ross single lens, 15 inches focus, $\frac{1}{2}$ -inch stop. His method of working resembles that of W. G. O., described in our last. He states that with a Fothergill plate he would obtain much quicker, although less certain, results. We cannot help thinking that by a modification of his method of working the tannin process, more rapid results might be obtained. See article in the present number by Mr. Hurst.

G. LEWIS.—The negative is very much under-exposed. Try a collodion containing double the proportion of bromide, or add at least a grain of bromide of cadmium or ammonium to each ounce of the collodion you did use. Let your tannin solution not exceed 10 grains to the ounce, and give a longer exposure. There are some interiors in which it appears quite impossible to get a good negative with a dry plate; with a wet plate, it might be desirable to cover up the plain glass window opposite the camera with dark cloth for the portion of the time of exposure.

AMATEUR.—The roof would be better in the form of the dotted lines, but the shorter half should be opaque. See articles in the present number. Eight feet will limit you somewhat in width; six feet more each way would be an advantage.

CHEMICUS has sent us a very pretty specimen of double toning. It consists of the portrait of a little child, the bright golden hair of which is kept very warm in tone, whilst the dress is of a warm or purple black.

A LADY AMATEUR sends us an account of an old camera, much resembling that described by Mr. Kirkby, as Matthew Boulton's. The date, 1843, was, of course, some years after the discovery of photography, but it is interesting to find a lady practising the art in a remote Scottish town like Moffat, so early as 1843.

JAVA sends us a piece of the varnished yellow paper used in diaphanic, which he finds the best material for the dark room window, being easily fastened to the glass, or stretched on a wooden frame. It is of a deep, rich yellow tint, somewhat resembling the colour known as Etruscan yellow. We will report next week as to its non-actinic character.

NEGATIVE.—It is difficult to form, from description, any certain idea of the value of such a room as you describe. A trial would be more valuable than an opinion, and the former you can easily make. Block up the window in the south end and place the background there. Then make a few trials with such light as you have, and send us examples of the results produced. We can then advise you as to the modification necessary. Your letter, which is dated Nov. 15th, only reached our hands this week.

G. M. RENAWAY.—Thank you for the copy of rules, which may be valuable in furtherance of the project.

F. W. EVANS.—Received, and will be acknowledged in due course. The other subject shall receive full attention in due course.

R. M. A Subscriber *ab initio*.—Your letter has been forwarded to "A Photographer's Assistant," and you will doubtless receive a reply in due course. Some delay may arise from the letters being sent to him altogether and not singly, as received.

A. B.—You will be able to get Turner's negative paper of some of the dealers, but we are uncertain of who may have it in stock. We cannot tell you the wholesale price of transparencies.

NIL DESPERA VIDI.—The prints have been fixed, or rather imperfectly fixed, in old hypo; some traces of hyposulphite of silver have remained in the print, and subsequently become decomposed. Damp would facilitate such decomposition.

ARTHUR GREEN.—The cards are very interesting, and the lighting very good. Several Correspondents in our next.

ERRATUM.—In the letter on "Reduction of Residues by London Refiners," in the NEWS for December 4th an error occurs. The cost of 380 ounces of nitrate of silver at 3s. 5d. should have been stated as £64 18s. 4d., instead of £64 18s. 4d., showing that the offer of 380 ounces of nitrate of silver in return for 350 ounces of chloride of silver was a very liberal one.

PHOTOGRAPHS IN PRINTING INK.

Mr. Poncey continues to progress in perfecting his last carbon process. He has recently given a practical form to a most important improvement. In our first notice of the results, we stated that the chief drawback consisted in a somewhat unsatisfactory colour, and in the necessity for using a thin transparent paper, which materially detracted the artistic effect of the finished picture. In both these respects considerable improvement has been made.

In our earliest experiments with the prepared paper, we found that much of the dingy olive tint which seemed to pervade the blacks and half-tones could be avoided, if the transparent print were mounted on a paper possessing a very delicately pale tint of pink. This seemed to change the whole tone of the picture, without suggesting the presence of colour in the lights. We suggested this improvement to Mr. Poncey; but, at the same time, expressed a conviction that a method of transferring the print from the thin transparent paper, necessary for its production, on to a more suitable ground, would be the most desirable improvement. In the recent specimens we have received, he has combined both these improvements, and the pictures, card portraits, are barely distinguishable from silver prints.

In order to render the transfer easy, a slight modification in the preparation of the paper has been necessary, and experimentalists wishing to obtain such a result should, in ordering paper, expressly state that it is required for the transferring process. The printing operations are the same as those already described in our pages. The completed print is then attached, the inked side downwards, to the mount of delicate pink, with some adhesive material not readily softened again by moisture. The best substance is still a question for experiment. When firmly attached and dry, the surface is sponged gently, the thin transparent paper at once becomes detached, and may be lifted away, leaving on the mount a perfect impression in printing ink, with every gradation of half-tone possessed by the negative.

At present there is some difficulty in procuring the suitable mounts, and it is necessary, to secure the best tint, to use paper for the transfer, mounting this subsequently upon cards in the usual manner. The steady perseverance and skill with which Mr. Poncey devotes himself to overcoming obstacles, and improving his process are worthy of all praise, and we hope his efforts will be eventually crowned with the success they deserve.

ON THE COMPARATIVE VALUE OF THE DAGUERREOTYPE, COLLODIOTYPE, AND CALOTYPE PHOTOGRAPHIC RESULTS (AS REGARDS PORTRAITURE) IN POINT OF BEAUTY, PERMANENCE, &c.

BY JAMES EWING.*

In looking over the exciting history of photography—from the last great act of instantaneity (viz., the making of a

picture in the 1-36th part of a second) to the time when the greatest minds of the period were delighted with the phenomenon of the darkening of lunar caustic or horn silver; or, further back still, to the accidental moment, fraught with one of the greatest wonders of the future,—that quiet oen in which Porta, the artist, discovered the inverted picture of the outside scene on his darkened studio wall,—that which led to the construction of the *camera obscura*, and first awakened the desire to obtain on its whitened sheet the images which the light reflected—we find the engrossing desire steadily maintained through the whole of the archives was “how to attain the image of man.”

Wedgwood and Davy were delighted with the results they obtained on simple nitrated and chlorided papers, and glowed with enthusiasm when showing their friends, by the dull light of a taper, negative pictures of opaque or semi-transparent subjects. That was in the year 1803; and already had the desire begun to assume a practical form, for we find at that date, exactly sixty years ago, a paper published in the “Journal of the Transactions of the Royal Institution,” by Wedgwood, with observations by Davy, entitled “An Account of a Method of Copying Paintings upon Glass, and of Making Profiles by the Agency of Light upon Nitrate of Silver.” Here already was an attempt to cut out the black profiles of the day, without the assistance of the camera, by reversing the colour of the profile, having it white on a field of black.

The camera was adapted to give subjects from nature, but the chlorided paper was found too insensitve to make pictures by reflection; yet the great Davy succeeded in making images by means of the solar microscope. Thus, long before the time of Mr. Talbot, chlorided paper was used in the same manner as it is used in the solar camera of the present day.

Niépce followed up by placing his resinized surfaces in the camera, and obtaining faint images of architectural and natural subjects; but as yet man had not graced the photographic tablet through the medium of the camera. About this period, however, the magician Iodine was raised from the laboratory of nature to work the spells of photography. The artist Daguerre summoned this geni of the camera to his aid; and soon after, to the astonished world, he made the invisible to become apparent, and produced the wonderful sun-picture!

Yet the optical apparatus was far from admitting of a portrayal of the lord of creation; and it was in 1840 that a gentleman in New York, by using a lens of larger aperture and shorter focus, succeeded in obtaining the first portrait in Daguerreotype. Lucky fellow he must have been, to be the first whom the loving sunbeam condescended to enshrine in mirrored memory! Thus, at length, the charm was broken. That man was the first to mark a new epoch in portraiture, more beautiful and more truthful, but, alas! less permanent, than its canvas ancestor.

It would thus appear that the art was considered incomplete till it properly represented “the human face divine”—that last and finishing work of an Almighty Artist. Portraiture, then, is one of the great branches of the art; and

* Read at a Meeting of the Glasgow Photographic Association, Nov. 11th, 1863.

any process which the art involves, that gives the most beautiful and permanent results, must be considered the most valuable as regards the portrayal of humanity.

In point of beauty, then, it appears to me that no process gives such fine results as that of the Daguerreotype, seeing that it fulfils all the requirements desired by those who have in any measure studied the aesthetics of this particular branch of photography. By it, the most life-like pictures have been made; in fact, one of our local artists used to advertise "speaking likenesses." Without endowing them with the faculty of speech, and, at the same time giving the artist his due, they were very telling portraits. Many of his, and of many other artists who were then practising the art here, come before me yet to be copied or cleaned; and I can assure you they come like "sunny memories," reminding me of a time when really pretty pictures were made by a process much revered, but now superseded. There was a roundness and depth given to the subjects which I have never seen equalled by the other processes—a sharpness, minutæ of detail, clearness of line, and, with all this, a gradation of light and shade softly delicate. They seemed to reflect the beautiful image of one's friend in a mirror. You might fancy you could touch the reality, so quietly did the background recede from the figure. Now-a-days the background comes up to the utter exclusion of the figure, which seems to have some connection with a furniture warehouse in the distance; or that it dwells in "marble halls," being a mere statue in the centre. Moreover, there was a warmth and brilliancy about the Daguerreotypes which all the toning baths of the present fail to excel. Pretty pictures, which have had their meed of praise awarded them in being likened to the Daguerreotype, have been produced by the collodiotype; but the calotype pictures will in no manner bear comparison, so different are they in make and appearance—the one being the direct heir of the camera, the other the effect of light thrown from its parent's shadow. In them there is a want of that softness possessed by all the other requisites which the silver plate had, and which I fear can never be rendered in sombre black and white without being placed on a reflecting medium.

The second great quality in a photograph is permanence; nor can we wonder that such is desired in those light-formed images so beautifully true. All that we can wish for next to the original is there:—each line correct, each feature given; the grey hair, with its peculiar curl; the thoughtful eye, with its quiet look; even the individuality impersonated in the pose; and where such pictures are aided by binocular effects, how wonderfully true! Before such the poet and painter must bow, and the sculptor resign his chisel. The curious, cunning work of the sunbeam cannot be rivalled when joined with optics in such illusion that cheats the sense of sight itself, and from flat planes raiseth before us in palpable form the beings we love. It is a sad thing to think that those pictures which thrill us with their truth and fidelity, and which seem to spring from the invisible, should, after a short sojourn in the land of figures, again return to invisibility. We can fancy the first photographer's emotions as he stood entranced scanning the images that used to scamper across his camera glass now captive held at last, and immediately after perplexed with the thought of how to stay their visit—at that time a very transient one, as the hyposulphite of soda had not yet been applied. His feelings, somewhat modified, may still apply to our own, as our further discussion of this subject will show.

The calotype—or more properly speaking paper photograph—has many advantages in its favour, that of reproduction being one of its most important features, as also its portability and adaptability to a variety of uses. It permits of being used without case or frame, and if it fall, it is not easily broken. Certainly, these are great recommendations; but, unfortunately, it sadly lacks permanence. Toning baths have been devised for the colouring and the rendering more permanent of the image obtained on the chlorided surface.

These have the power of extracting a portion of the reduced chloride, and of substituting gold instead; thus the original image, built up by the light, is partially removed and something else added. I have often wondered whether this doing and undoing does not affect the stability of the image, as I have for a long time past had by me prints taken from the printing-frame, which, after having been washed, and passed through the hyposulphite of soda bath, look as bright as on the day they were dried. Of course their colour is not so charming as those that had passed through the gold-toning bath, being red: but they have the excellence of being more permanent, as placed before their darkened brethren of the same date. They retain their red and white, whilst the blacks of the others turn to a leaden colour, and the whites to that delightful colour which allows us to work in darkness and concerning which there is so much darkness. Of course your old antagonist, the hyposulphite of soda bath, is blamed: your prints have not been properly washed. But why do the red prints retain their whites, whilst those that have had the deep violet tinge added to them, assume such a faded appearance? This is a question I should like answered, or at least have you to think over, as you know the old hyposulphite of soda bath has long been in disrepute the *sel d'or* reckoned only a little better, whilst the alkaline gold-toning bath has had a fair trial, and still the voice of truth proclaims our work unstable. The Exhibition test was a tough one; and I see a motion is being agitated by a certain society for the purpose of storing up the effigies of the notables of the present, only the members do not know well how to proceed, as this stumbling-block of impermanence stands in the way, and cannot be readily got over. In the plain paper prints there was a tendency towards the image sinking in the pores of the paper, which in a great measure was obviated by the instituting of albumenized paper; but this albumenizing has brought on a host of difficulties which have to be contended with, the greatest of which seems to be in the fact that a portion of the silver employed in the formation of the picture cannot be extracted by means of the hyposulphite of soda bath, and consequently must tend to the impermanence of the print.

It is unfortunate that so much can be said against this division of our comparison, as it is the most generally useful and workmaking branch of the whole profession.

We shall now turn to the collodiotype positive, the formidable rival of the Daguerreotype. It could be looked at in any light—give the image non-reversed, if required, but seldom done—could be coloured, and, more, varnished; but its great recommendation was that it could be made the medium from which any number of copies could be thrown. It will be observed of the glass that it did away with the old paper negative "botheration." Like the Daguerreotype, however, these pictures had to be kept in case or frame. By this process many beautiful portraits were made; but until they were varnished their permanence was much less than that of the unglilded silver plates, such instability arising in many cases from the different developers used. As, for instance, a picture the silver of which, from rapid development, was thrown down in large flakes, spongy and white, would not endure in the common atmosphere so long as the development of which was prolonged, the minute particles of silver precipitating in a more metallic form, and when finished assuming more of the colour of a good Daguerreotype—a clean, frosted silver appearance, with the high lights and deepest shadows given without that hard dash of black and white too characteristic of this process; but the necessary black varnish was difficult to obtain that should possess the good quality of not cracking or becoming powdery, as is the case with most varnishes after the volatile oil with which they are impregnated vanishes, the resinous substances left breaking up into thousands of ridges. Such was the case with the black enamels used in backing of collodiotypes. Cloth and paper were often substituted with less effect. This unfortunate cracking was over the cause of pictures being brought back to the photographer as spoiled

and faded, and yet the customer would remark that they "had not been kept in a damp room." The transparent varnish in front of the pictures, which promised great permanence in the subject, and which caused many operators to advertise "everlasting photographs," also gave way; and, in the case of soft precipitates, the oil in the varnish permeated the soft film, giving an unpleasant tone to the picture, and eventually running into streaks. This process, however, has given more permanent results than its offspring, the paper, and many beautiful collodiotypes are scattered over the land. Of course the process of making the negative of the present is nearly one and the same, the black varnish being omitted; yet the same difficulty is felt in regard to the transparent varnishes used, as they often crack the film containing the picture, which, if you attempt revarnishing, ten chances to one you do not carry away the whole substance forming the negative. Yet the collodiotype has conferred a great boon in even producing for a short time positive results on paper which, if we could only retain them in a permanent form would indeed be valuable.

We now come to the startling process which first awoke the world to the practicability of retaining images given by the camera, viz., the Daguerreotype—the only real dry process that has given satisfactory results which cope with and, in my opinion, far supersede any process yet known, wet or dry. True, instantaneous pictures could not be had by it. True that, if rubbed or exposed to the air, certain damaging effects must ensue. Yet, as true is it of the Daguerreotype that no other process has given such satisfactory results, applied to portraiture, in point of beauty, permanence, &c. This may seem a sweeping assertion, but I shall, after a lengthened acquaintance with the processes named, endeavour to prove its admissibility; in fact, it appears to me that the very nature of the process will bear out my argument, being so far different from that of the calotype and collodiotype, the images by which are the result of silver in a weakly reduced state, held in a mechanical manner on the surface and in the pores of two substances that have no chemical affinity for the metal, and only hold the molecules of it as a sponge does water, so loosely put together that the slightest disturbing influence alters its condition. In those processes, too, it is difficult to get rid of the chemicals which acted in the formation of the image, and which, if the slightest trace be allowed to remain, is sure to produce decay—decay which twelve hours' washing under a running tap, with all the recent forms of tubs and dripping apparatus, have failed to cure, and I doubt ever will. In the Daguerreotype the case is materially altered. You have the pure silver surface—the metal, in fact, to work upon. You use the chemicals required in their purest form:—the iodine evaporating from its crystal; the element, bromine, also in a state of vapour. These rise to the surface of the pure metal; they sensitize the plate, which, after exposure in the camera, is brought back and developed with the vapour from the pure element, mercury. Again, after passing through the decolorizing hyposulphite of soda bath, it is coated with the pure element gold. You will observe that all the elements forming the Daguerrian image are pure natural products, uncontaminated with any secondary material, the metals used having a powerful chemical affinity for each other. Mercury, ever desirous of forming an alloy with silver, becomes the medium in its joint condition to mingle with the gold, thus building up a compact image of three noble metals, each and all difficult to oxidise in a pure atmosphere. Still further, the tablet, being of pure silver, admits of no chemical action from the back, and of no decaying element from within. All decay must be in front. The varnish of gold must be first attacked by atmospheric influence. This gilding, being carefully deposited over the whole plate, and not on the metal forming the immediate image, as in the calotype, is difficult to oxidise, and that so slightly that long-continued action from simple natural causes make small difference upon it.

We now come to what we mean to use as a test on these three photographic results, and it is this:—The Daguerreotype,

often from being badly glazed, exposed to a bad atmosphere or damp, becomes coated with brown or blue hazes, which for a time dims its beauties, many thinking that it has faded away; so also does the collodiotype, and there is no doubt about the calotype's fading propensities. Now, in the case of the Daguerreotype a certain strength of cyanide of potassium, carefully administered, restores the image at once to youth and beauty. Try the same on the collodiotype, however little oxidised, and it begins to assume the dissolving principle of Mr. Pepper's ghost, which, after the exhibition, leaves only a glass behind. Test the paper images in the same manner, those fixed in the old hyposulphite of soda bath, the *sel d'or*, or the alkaline gold toning bath—so forcibly spoken of over two years ago—and you will find that all accept the cyanide as their "ticket-of-leave."

In making this comparison I have endeavoured to show up the somewhat neglected merits of an old (and in point of permanence, tried) process, without saying aught of the other processes but that which is true. And my desire in doing so is to stimulate you to greater endeavours in the making of those truthful resemblances which, however large or fine, if they want the quality of permanence, can never be esteemed as they deserve; and if, from what has transpired in the past, we can learn or suggest something better for the future, much good will be accomplished. Such is my apology for these remarks.

THE BIRTH OF AN ART.*

BY GODFREY TURNER.

There was once—not so very long ago but that people now living can remember seeing his works as they were newly exhibited in London, Paris, and other great cities—a man who carried a certain skill of illusion to so marvellous a pitch, that he could in one picture show "the season's difference," the changes of day and night, and besides all kinds of natural phenomena, the progressive effects of devastating fire. His faculty being merely imitative, it was said that he had "no art." That is a question we need not argue in this place. For the present purpose it is enough to say that this man could set before us a natural scene—in all respects natural. The spectator sat in a darkened room, one end of which seemed open to the free air and a wide expanse of country—let us say, an English landscape, though the range of the artist's subject (we may call him "artist" for the nonce) was as various as in each picture were the aspects which half an hour would seem to bring about. There are corn-fields, and a homestead, and green trees, and the tops of village roofs, and an old church tower; and there is a brook in the foreground, with a deep still pool, darkened by overhanging boughs. The water glides, and ripples, and glistens, and lies still, not with mechanical sameness and repeated obtusive trick, but variably, and with the quiet, constant air of nature, half in motion and half in repose. There is a wooden bridge, and its reflection in the stream actually follows every little trembling movement of the surface, and is even true to the influence of every passing cloud. It is early summer time, and clouds are passing, just as if the blue beyond were sky and not painted canvas. They gather, concentrate, and pour down rain. The effect is so thoroughly natural that you listen for the splashing in the water. Every drop is seen distinctly to fall like a plummet on the face of the brook and on the face of the pool; but it falls with strange, unaccustomed noiselessness. The heavy, down-pouring streams now begin to slant, and the tops of the trees to stir and bend. The highest branches are flattened together, and they start and stoop, and stoop more and more, as the wind appears to be gaining strength, and to drive the rain sidelong, ruffling the waters. A flash—a sudden lull in the storm, and a gradual dispersing of the clouds, while another flash and another succeed. A rainbow shows that

* *Everybody's Journal.*

the summer tempest has passed, and now the sun shines out again upon the leaves and the grass, wet and glistening.

More changes follow over the same landscape.

A summer sunset, a mellow harvest-moon, paled by the sudden blaze of distant hayricks.

A bright December day, dying in the gloom of a cold December twilight, the waters freezing as we look; a snow-storm shrouding the dead ground; early spring again, and cheerful sunshine and budding trees.

So with other scenes. The artist, defying—or, perhaps, knowing nothing of academic rules of art—constantly presented to our wondering eyes the most perfect imitations of natural effects. All “cosmoraucic” attempts which have followed those we speak of are mean, bungling, and coarse by comparison. The great mass of spectators admired unquestioning, and freely indulged their common love of wonder. Artists even would snatch a fearful joy, and ease their consciences afterwards by making severe remarks on trickery and realism, and the falseness of combinations. Meanwhile, the man went on “combiuing,” and crowds were still delighted.

But he was not quite satisfied himself with the results of his toil; such truths as he had discovered in the course of his researches in chemistry and optics had given him a new idea. These transitory aspects of nature, these constant changes which give beauty to commonplace, and which, taken away from beauty, leave it cold and grim—was it not possible to arrest them, to collect the rays of their reflected light in a camera, and fix the image on a tablet? He told his wife the awful thought, and she turned pale. It is an authentic fact, that one night, after going with her husband to hear a scientific lecture, she contrived an interview with the lecturer, drew him apart, and with painful agitation implored him to tell her whether the fancy her husband had taken into his brain was the fancy of—a maniac! The professor smiled, and consoled her by saying that her husband's visionary idea might one day be found practicable enough.

This man, then, who dreamt the poet's dream of retaining beautiful shadows; this madman, as his anxious wife, reasoning with the world's reason, deemed him—this no-artist, who so loved nature, was named Daguerre. His dream was the Daguerreotype.

That your philosophy, and especially the practical kind, falls a little short in its calculation of the things that are in heaven and earth, an obscure dramatic poet has ventured to assert. It is a pleasant, certainly not a strange, coincidence, that he who noticed that little failure of philosophy should have attached an almost substantial value to shadows. In one of his plays—“A Midsummer Night's Dream,” it is called—the word occurs an extraordinary number of times, and always accompanies some graceful plea for fancy or imagination. This play has a quaint epilogue, spoken by a fairy, and beginning with the language, “If we shadows have offended.” It is a most charming piece of supplication. The noble and dignified good nature of one of the characters in this said play—a mortal and a duke—puts the same thing in a more human way. Another of the *dramatis personæ*—a lady—is very hard on a certain “tedious brief comedy,” setting forth the loves and sorrows of Pyramus and Thisbe, with their sad ending; and this kind-hearted potentate meets her ridicule with a reply which ought to be written over the proscenium of every theatre. “The best in this kind,” says he, “are but shadows, and the worst are no worse if imagination amend them.” The finest part of the matter is that this Duke Theseus is an eminently practical man in his way; that is, he is a man of decisive action; and he has no transcendental notions that we hear of. He belongs to the governing class; he hunts, enjoys himself, gets married, all in a splendid fashion, and with an absence of untoward circumstance which is quite prosaic, when the troubles and vicissitudes of the other characters in the play are taken into consideration.

The author of that play himself—one William Shaks-

peare—was not a bad instance of the fusion of ideality and business. Amid a great deal that is not at all certain in his biography, there is at least one thing that is. He made a will. Further, it is quite plain that he really had something to leave out of earnings which, considering the nature of his work, we may regard as the tangible results of imagination—the substance pertaining to the shadow.

It may be worth while to recollect such things whenever we pass that most common of street objects, a photographer's case of specimens. From a shilling portrait on glass, “including frame,” to the most perfect and artistically beautiful miniature by Dickinson or Lock, the present writer may truly say that he can never look at a photograph without its calling to his mind the material uses of imagination, and the birth of a new art in the brain of Daguerre.

LIGHT.

In analyzing a ray of light, if the spectrum be divided into 360 parts, the red will occupy 45 parts; orange, 27; yellow, 48; green, 60; blue, 60; indigo, 40; violet, 80.

Light travels at the rate of 192,500 miles in a second of time, according to Herschel.

In the prismatic spectrum, violet rays indicate heat as 1, green as 4, yellow as 8, and red as 16. Beyond the red no peculiar action exists.

The colours of bodies depend upon the size of their atoms, and the chemical character of the local atmospheres of their atoms and interstices. Black has small atoms, and absorbs light; white large and reflects it. Reds are of oxygen character, according to Ellis; greens, nitrogen; and violet, hydrogen. Their minute parts decompose incident lights, absorb some, and reflect others; an oxygen body combining with hydrogen, and reflecting red; and the contrary with others; thus a hydrogen atmosphere absorbs red, &c., and reflects blue and indigo, &c; and a nitrogen absorbs red and violet, and reflects green or white, orange or blue.

The complementary colours are—for black, white; white, black; red, blue green; orange, blue; yellow, indigo; green, violet red; blue, orange red; indigo, orange yellow; violet, bluish green.

When the shadows of the same object projected on a wall by two lights are equally dark, the lights themselves are equally intense; but if not, the darkest shadows will be protected by the interruption of the brightest of the lights; and if this brightest light be then removed further from the wall, till both shadows become equally dark, and the distances of the lights from the wall be measured in that situation, the intensity of each will be in proportion to the square of its distance. For example, if two lights give shadows equally black or dark, when their distances from the wall are respectively five and seven feet, the intensity or quantity of light omitted from them will be respectively as 25 (or 5×5) and 49 (or 7×7).

Bodies which refract most reflect most, or are more splendid. The local atmosphere which increases one increases the other.

Reflection is in intensity as difference of refractive power in the media.

The full moon produces no heat.

The optic nerve enters the eye .11 of an inch from the axis of the eye, on the nasal side; the axis is .91.

Angle of vision taken in by the fixed eye, 110 degrees.

Impressions on the eye are permanently continuous which are repeated 7 times in a second. When the sea is a blue colour, it is deep water; and when green, shallow. The film of a soap bubble about to burst is only about three-fourths of the millionth of an inch in thickness.—*Scientific American.*

FADED PRINTS.—The action of bi-chloride of mercury in restoring faded prints will be discussed at the next meeting of the North London Society. Mr. Godbold will read a paper on the subject.

Correspondence.

THE ALLEGED EARLY PHOTOGRAPHS.

SIR,—Respecting Mr. James Watt's progress in photography, I find an extract in the *Mechanics' Magazine*, August 30th, 1823. First article, 1st No. and 1st vol., which may be interesting to your readers.

In a "Memoir of James Watt," the writer quotes the words of "One who knew him well," and continues:—"After the year 1817, he applied himself, with all the ardour of early life, to the invention of a machine for copying sculpture and statuary, and exhibited his performance amongst his friends, as the production of a young artist just entering on his 83rd year."

It may be interesting to find who this authority is. The magazine gives no further trace.

I take this opportunity of expressing my thanks for the information I have received from your very liberal and valuable journal.

Since taking it, I have been quite an enthusiast in photography.—I am, Sir, yours very respectfully,

JOSEPH PODMORE.

Oxford, Dec. 21, 1863.

ELECTRIC LIGHT FOR PORTRAITURE.

DEAR SIR,—Mr. Busch has somewhat misunderstood me in supposing that I had, in my experiments with artificial light for photographic portraiture, used a Ruhmkorff's coil; indeed, at that time it had not been invented. In a somewhat extended series of experiments, undertaken at a time when the Daguerreotype process was the only method used for photographic portraits, I tried many forms of artificial light, amongst which were the electric light, the Bengal light, the Drummond light, and others, but in no case with perfectly satisfactory results. The electric light was most actinic, but was too intense and concentrated, and produced the usual result of an intensely brilliant direct light; it gave chalky lights and heavy black shadows, and by rendering it impossible for the sitter to sit with open eyes, was destructive of expression. With the less intense lights the difficulties were lessened, but the exposure was more prolonged, rendering them unsuitable for portraiture.

Amongst the various experiments tried was the natural one of using screens for diffusing and reflecting the light, which effected some improvement; but the final issue of my experiments at that time was decidedly unfavourable to the employment of any artificial light for photographic portraiture.—Yours, dear sir, very truly,

T. R. WILLIAMS.

236, Regent Street, Dec. 21, 1863.

THE TANNIN PROCESS: IS IT SLOW OR RAPID?

DEAR SIR,—Mr. T. Hurst, by his able and intelligent comparison of the tannin process, as practised by "G. W. O." and myself, has anticipated the remarks I intended making on this interesting subject.

I will here add a few more details of my method of working, as it is only by careful comparisons of facts that it is possible to arrive at more correct conclusions respecting the capabilities of this beautiful and simple process. I am unable to supply any information as to the amount of bromide contained in the sample of collodion I employed; I believe it to be considerable; in fact, the bromide ought to be in as large a proportion as possible, consistent with easy and quick manipulation, plain bromized collodion being rather too slow in getting thoroughly decomposed in the nitrate bath, to quite please me. My bath was the usual 35-grain one, containing 15 drops of nitric acid (sp. gr. 1.360), in 40 ounces of solution; at the time of using it, it had had about 60 half-plates sensitized in it.

As you will easily perceive, this was very acid, but as I

found a neutral bath gave me rather foggy plates, I preferred keeping on the safe side, especially as I did not find any appreciable loss of sensitiveness occasioned by this degree of acidity.

It is my impression that the plates are more sensitive when the tannin solution has remained on the film for some little time; some plates prepared in my usual way, but simply coated four times with fresh tannin, were very slow, and gave fog and stains in the lower part; those on which the tannin solution remained for 2 minutes, were clean, but certainly not so quick as those coated for five minutes or more. When my time permits, I intend trying the effects of an iron developer, of course taking care to wash off all the tannin, before developing, with plenty of water or dilute alcohol. Perhaps also the process could be reversed, so to speak, a plate being coated with collodion containing nitrate of silver, dipping it in a solution of iodide and bromide, washing and coating with tannin. This might be found to have some advantage in the greater rapidity of preparation, as the adhering weak solution of iodide and bromide could be more easily washed off than the nitrate of silver. They would perhaps be very susceptible to the actinic influence; the plates would thus be "sensitized" by the tannin which it is said, "renders them as sensitive as by nitrate of silver."

For the present, however, I am well content with the tannin process, *pure et simple*. In conclusion, I am glad to say that my experience enables me to endorse fully Mr. Hurst's remarks and summing up.—Believe me to be, dear sir, yours very truly and obliged,

H. C. JENNINGS, junr.

London, Dec. 22.

SOUTHWELL v. ORDISH.

SIR,—In your Journal of yesterday's date, you refer to the above case, recently heard before Alderman Carter, and remark "that the decision given is, not unnaturally, very unsatisfactory to the plaintiffs," &c., &c.

It struck me on reading a report of the case in the *Daily Telegraph*, that no evidence was offered before the magistrate showing that the Messrs. Southwell had reserved to themselves the copyright of the photographs in question by agreement in writing signed at or before the time of such sale or disposition by the vendor, &c., &c., in accordance with the provisions of the 25th and 26th of Victoria, cap. 68, sec. 1. It was stated that Messrs. Southwell claimed the copyrights of the portraits of Miss Thompson and another because they took them from the living originals.

I need not remark to you that this, *per se*, will not meet the requirements of the Copyright Act.

If A. B. is paid for taking the photograph of C. D. in the absence of the written agreement referred to in the Copyright Act, no right of property in such photograph can be legally claimed by A. B.—Yours obediently,

AN AMATEUR.

December 19th, 1864.

[The first section of the Act is somewhat obscurely worded; but, if we understand it rightly, no agreement or signature is required where the artist takes the picture for himself. It is then his, and if he registers it, no one may copy it without his permission. If, as our correspondent remarks, A. B. were paid for taking the portrait of C. D., then, in the absence of an agreement, no copyright would be obtained by either party. But, in the case in question, C. D. does not pay A. B., but sits for A. B. at his request, and for his purpose: in some cases C. D. is really paid by A. B. for the sittings. In such case we have no doubt the copyright is legally vested in the author of the work, and no agreement is required until he sell a negative. See the Act, first section, "Provided that when any painting or drawing, or the negative of any photograph shall be for the first time after the passing of this Act sold or disposed of," &c.—Ed.]

Photographic Notes and Queries.

GLASS ROOMS.

DEAR SIR.—In reference to W. B. Parker's paper on "Glass Rooms and Lighting the Sitter," we beg you to inform your numerous readers, that we are not in the habit of dancing our sitters about the room to get them properly lighted.

We would advise W. B. Parker, in future, not to make dogmatic assertions of people, before he knows something of their antecedents, and of the facts of the case.—Yours truly,

HELSEY AND CO.

34, Church Street, Liverpool, December 22, 1863.

Talk in the Studio.

PHOTOGRAPHY IN PARIS.—The rage for photography, and especially for "cartes de visite," is now furious in all quarters of Paris; indeed, in many streets, the houses are about equally divided between shops where they sell "comestibles" or diverse drinks, and those where you can have your "counterfeit presentment" taken for sums varying from one franc to one hundred. A few days ago a *porteur d'eau* presented himself at the studio of one of the most eminent photographic artists, and said, "Monsieur has taken the portraits of the Marquis and Marquis X., and their daughter?" "Perfectly," replied the artist. "Will then, Monsieur, be so polite as to give me copies of them, as they alone are wanting to complete my album of customers." I have said it is a rage, and so it is; no age or personal appearance can stop the fever of photography. The wife of my concierge, who is not in her *première jeunesse*, and who even, when she was, could have scarcely been a beauty, is to-day having five francs' worth—frame included—to give her husband on the *jour de l'an*. Even those who wish to avoid the operation cannot, as they are enticed into a studio, and "negatived" before they can say "no!" It is not a pleasant operation either, this being photographed; indeed it produces a disagreeable recollection of youthful visits to the dentist. An intensely hot room—dark, except where a blinding ray of light, destined to be turned full on to your eyes, streams through the window; such is the scene of suffering. Now for the suffering itself—you take a seat on an uneasy chair, an instrument of torture is applied to your occiput, a table is pushed "artistically" into your left side, a strong man moulds you as he would a lump of clay, "your head, there! good—half close your left eye! there, charming. There, there, good, beautiful, your arm. Ah! a spasm; that will pass. There, good, your foot, ah!" and having undergone this mild but irritating torture for twenty minutes you are told to "look pleasant" for ten more while the artist studies your inverted figure. "We must suffer to be beautiful," says the French proverb, but speaking from personal experience I must say I have undergone the conditions without obtaining the result. In spite of this, however, the "Beautiful"—spelled with a big B—is so inherent in some natures that I have actually to-day seen four photographs, not only good but pleasing.—*Paris Correspondent Daily Telegraph.*

REDUCTION OF CHLORIDE OF SILVER.—MM. Millon and Commaille have communicated to the French Academy of Sciences, an extremely elegant reaction, by which absolutely pure metallic silver may be precipitated from its ammoniacal combinations, with all the accuracy necessary for rigid analysis, and in such a division as to render it available in the arts. The reagent employed is ammonio-subchloride of copper. When this substance is added to ammonio-nitrate or ammonio-chloride of silver, the whole of the silver is at once thrown down in the metallic state as a grey amorphous precipitate. The precipitate readily assumes a metallic lustre under the burnisher, and may be applied to the surfaces of wood, stone, &c. The reaction takes place so perfectly, that it may be employed either for the estimation of silver, or for the analysis of a mixture of sub and protosalt of copper; every atom of silver thrown down representing gone atom of subchloride of copper. It is, however, especially valuable for reducing the chloride of silver residues of the laboratory. These are dissolved ammonia, and the ammoniacal subchloride of copper added, when the metallic silver is at once obtained in its purity. Moreover, it is only necessary to digest the filtrate with a little powdered zinc in a closed flask, in order to again reduce the copper salt, and it is ready for a fresh operation. In this way, the same quantity of copper solution suffices for an indefinite number of precipitations.

*^o PRESENTATION PRINT.—With the PHOTOGRAPHIC NEWS of January 1st, 1864, we shall present each of our subscribers with a beautiful specimen of Mr. Duncan Dallas's process of photo-electric engraving. This process has been universally acknowledged to be the most perfect method of photographic engraving yet discovered, possessing perfect half-tone and gradation with great force and vigour. The subject is the "Banqueting Hall, Kenilworth," from a negative by Mr. Francis Bedford, the size of the print just permitting it to be used as a page of the PHOTOGRAPHIC NEWS. The print will be from a plate untouched by the graver. It will be printed on toned plate paper, and will be valued as a charming picture, as well as an interesting illustration of a valuable process.

TO AGENTS.—As there is reason to anticipate a large demand of the No. for January 1st, agents are requested by the publisher to send their orders for extra copies as early as possible.

To Correspondents.

*^o With the present number, containing title-page, preface, and index to the volume, four pages extra are given, without charge.

THE GODDARD RELIEF FUND.—We have received several subscriptions for this fund, but are compelled to allow a detailed acknowledgment to stand over until our next.

C. UPROX.—You may keep a little kaolin in your filter, always allowing the silver solution to pass through it when returning it to the bottle. We do not use kaolin at all, preferring the mode of decolorising the bath by the addition of a few drops of a solution of salt and water. 2. There is no objection in adding fresh acetate of soda to a toning bath in use, but if you have done so accidentally, it will not do any harm.

NITRATE.—If, on adding nitrate of soda to your silver bath, the latter turned turbid, the nitrate of soda had contained some impurity, either a chloride or carbonate, probably the latter. Other nitrates may probably be used, but we have not tried them.

A. YOUNG AMATEUR.—Various samples of collodion are used by different photographers for use with the collodio-albumen process. Probably 1 or 5 on your list will answer your purpose. 2. A tripod should not be shorter than 5 feet 6 inches in height. The question whether it should be folding or rigid is purely one of convenience. Rigidity is desirable, but it interferes somewhat with the portability of the tripod.

A. G. GRANT informs us that he has used nitrate of soda in the printing bath at intervals, during the last 8 months, with success and without difficulty, making the nitrate for his own use. 2. We shall have pleasure in receiving the description of a travelling studio. 3. It not unfrequently happens that the same idea occurs to various inventors, quite independently. Others have also conceived a washing machine very similar to the one in question.

SHEFFIELD.—The imperfections of your prints proceed rather from the negative than from faulty toning. The negative is not quite sufficiently dense in the lights, and is a little fogged in the shadows. With a better negative you will find it possible to get better prints. Steady perseverance and care will overcome your difficulties, do not suffer yourself to be laughed out of your efforts to improve. We are glad you so appreciate our labour, and are obliged by your kind wishes for the season.

W. ABERDEEN.—The cards have been forwarded. The lighting is, we fear, in your positive, difficult to remedy. The toning and printing are pretty good.

M. WYNTER.—So far as we know, the lens, regarding which you make inquiry, is a really good and useful instrument.

F. LOW.—In order to secure the copyright in a photograph, it is necessary to register it before any copies are sold or disposed of. If any copies were put in circulation before you registered, you have lost your remedy. If any one sells copies of pictures in which you have a copyright, you must take proceedings before a magistrate.

P. VINCENT.—The red or brown tone of your developed print is the result of over-exposure and under-development. The cause of the spots is less certain, they may arise from some defect in the paper, they may arise from drying the excited paper before a fire or gas stove, and be caused by contact with sulphur.

LEX TALIONIS.—Your letter on our contemporary's invention of what he terms "oral literature," or, as you phrase it, "spoken writing," and on what he terms "sarcasm," is amusing enough to the few interested in the matter. To the majority of our readers it would be neither instructive nor interesting, and we cannot devote space to matter understood by, and interesting to, half a dozen persons. In answer to your question, we certainly never heard of "oral literature" before, but we don't care to undertake the task of pouncing upon and exposing every blunder we meet with.

AN ENGRAVER.—You may doubtless obtain information from the patent agent. We intend to make some further inquiries, and will publish anything of interest we may learn.

We go to press one day earlier this week, and a large number of correspondents are compelled to stand over until our next.

Photographs Registered during the Past Week.
